Summary

Overview of Volume 1 of Male Reproduction topics involves the sections of testis, development, endocrinology, male reproductive tract, male reproductive physiology, comparative mammalian male reproduction, and environmental toxicology.

Overview

Volume 1 is focused on male reproduction in mammals and has the correlated male reproduction in nonmammal species outlined in Volume 6 on Comparative Reproduction. The first section involves Testis Biology, as the testis is the location of spermatogenesis and source for the germline or spermatozoa, which allows propagation of the species. An overview and history of testis biology is presented followed by overviews of the structure and cell types in the testis. The detailed endocrinology associated with testis function and development is presented. The following section is on Testis Cell Biology that provides the cell and molecular biology aspects of the Sertoli cell that physically support the developing spermatogenic cells and Leydig cells that provide the source for androgens/testosterone in the male for testis function and a large number of other tissues in the male. The seminiferous tubules that are surrounded by peritubular cells and testicular macrophages in the interstitial between the tubules along with vascular cells are also reviewed. The spermatogenic cells in regard to structure, cell biology, and various cell–cell interactions are reviewed. The developmental aspects of the testis are reviewed in the male gonadogenesis and male sex determination chapters. The critical phenotypic and molecular aspects of the sex determination are reviewed. The subsequent pubertal developmental period is then presented. The adult testis physiology topics that focus on spermatogenesis, the associated syncytium, seminiferous cycle, spermiation, and the blood testis barrier are also reviewed. Methodologic reviews of testis cell and organ cultures and germ cell transplantation are presented. Finally, the physiological impacts of castration are reviewed.

The next major section deals with Male Endocrinology. The hypothalamus, pituitary, and testis axis is reviewed with subsequent chapters on the cell and molecular aspects of pituitary cells. Specific chapters on hormones, including Follicle Stimulating Hormone (FSH), Luteinizing Hormone (LH), Inhibin, Activin, and Androgen, are presented. The genomic and nongenomic actions of androgens, as well as dihydroxytestosterone (DHT), are reviewed. The associated androgen actions on somatic cells, brain programming, and aggressive behavior are then reviewed.

The Male Reproductive Tract section has a series of chapters for each organ and developmental process. The male reproductive tract fetal development is reviewed with a focus on Wolffian duct development. In the adult, the spermatozoa produced in the testis first enter the rete testis and travel through the efferent ducts to enter the epididymis. The structure, function, and endocrinology of these organs are reviewed. Epididymal sperm maturation is then reviewed considering the ability of sperm to develop the capacity for motility and the associated structural and molecular aspects of epididymis function. The epididymal sperm then move to the vas deferens for storage prior to ejaculation. The prostate is a glandular organ that produces components of the semen, and the structure, molecular, and endocrine aspects of prostate biology are reviewed. The seminal vesicle is the next male reproductive tract organ that also contributes components to semen, and the structure, secretion, and endocrinology of this organ are reviewed. The final male reproductive tract organ reviewed is the penis, and the structure, erection, endocrinology, and abnormalities are reviewed. The ejaculation and semen constituents are reviewed in the final chapter of this section.

The Male Reproductive Physiology section presents a number of key topics associated with male reproduction. This includes male pubertal development in regard to reproductive organ development and endocrinology. Male fertility in regard to sperm numbers, motility, and male reproduction senescence is reviewed. The roles of circannual and circadian rhythms are presented. The energetics, immunology, and nutritional factors in mammalian reproduction are reviewed. The regulatory roles of the pineal gland and vomeronasal organ in male reproduction are reviewed. Finally, the current knowledge of male contraception is presented.

The Comparative Mammalian Male Reproduction section is focused on a variety of different species. The nonmammalian species are presented in Volume 6 to provide a more complete comprehensive reproduction presentation. Volume 1 contains the major mammalian male reproduction chapters. An overview and then separate chapters on the cow, pig, horse, sheep, rodent, dog, cat, primate, and human are presented. The unique and conserved aspects of mammalian reproduction are reviewed. Finally, the assisted reproduction technology (ART) and contraceptive aspects in mammalian species are presented. A more human focus on ART and contraception are presented in Volumes 4 and 5.

The final section of Volume 1 involves the Environmental Toxicology of Mammalian Male Reproduction. The impacts and actions of testis toxicants are reviewed. Environmental factors such as temperature, metals, and steroids are discussed. The various endocrine steroids and associated antiandrogens or antiestrogens are discussed. This includes endocrine disruptor toxicants like the plastics derived, bisphenol A (BPA) and phthalates, and pesticides. The influence of these factors on paternal exposures and preconception exposures on offspring are reviewed. The epigenetic transgenerational inheritance impacts of environmental factors in male reproduction is presented. Overall, how these environmental factors impact the male reproduction is discussed and reviewed.

The breadth, quality, and educational impact of Volume 1 of the Encyclopedia of Reproduction is solely due to the chapters' authors who are internationally recognized authorities on the topics and contributed significantly to the scientific advances in the field. All are active researchers who have made major contributions in the area of Male Reproduction. The contributors to this volume are very much appreciated.

Introduction

The objective of this article is to provide a number of early historic observations and theories that influenced the development of the field of Male Reproductive Biology. The use of castration by ancient man to domesticate animals indicate the testis was the first organ studied in regards to its impact on male reproductive physiology. The differences between males and females also lead to the first biological theories on why these differences exist. One of the first uses of the microscope was the examination of sperm and the initial theories developed that impeded the initial theory of fertilization. The basis for sex determination was also one of the first biological considerations of Aristotle which impacted the biological sciences for over 2000 years. This article will present a number of historic considerations (**Table 1**) that were for the most part inaccurate and misleading, but have significantly impacted the progression of the field of reproductive biology.

Historic Castration (Testis) Considerations

Ancient civilizations used the removal of testis (i.e., castration) to domesticate animals including pigs, cattle, and sheep. The origins of castration, most likely developed at the time of the emergence of farming (i.e., neolithic period ~10,000 BC), either accidentally or intentionally are unknown but had a significant impact on ancient civilizations ([Diamandopoulos et al., 2005](#)). Therefore, this biological manipulation is the first documented physiological observation on the impacts of a specific organ on the biology of an organism. The first writings on castration was around 1500 BC by Assyrians in a tablet relating castration as punishment for sexual crimes. Then, the Greek medical writer Hippocrates in the 5th—4th century BC elaborated on the concept requiring the two parents. Physical traits on voice and feminization in eunuchs (i.e., human castrations) were documented by Aristotle in the 4th—3rd centuries BC ([Hippocrates, 1915](#)). He commented on the effects of castration in the rooster and man and gave a detailed description

Table 1 Historic considerations impacting male reproduction

<i>Reproductive topic</i>	<i>Observation</i>	<i>Period</i>
Castration	Testis first organ interest Domestication animals Eunuch characteristics	Prehistoric/neolithic Assyrian/egyptian/greek societies
Reproduction theory	Theory male provide seed (testis involved) <i>active</i> role and female provide soil <i>passive</i> role (prevailing theory 2000 years)	Aristotle (384–322 BC)
Environmental sex determination	Theory environmental factors such as heat (fire) and cold (water) promotes sex determination for male or female	Aristotle (384–322 BC)
Spermist theory/animalculism	One of the two theory of preformationism for which sperm head contained preformed offspring (homunculus) and female provide passive environment for development	Nicolaas Hartsoeker 1600s
Ovism	The other theory of preformation for which “the embryo is preformed in the ovum (egg) while the sperm only provides an aura seminalis,” that is a vital essence	1600s–1700s
Female ovary and egg role reproduction	Egg produced in ovary and has active role reproduction with sperm	William Harvey and Bishop Niels Stenson 1600s
Male reproductive tract organs anatomy	Detailed anatomy of male reproductive tract organs and specialized roles	Vesale 1543s and De Graaf 1600s
Genetic sex determination theory	The role of genetics followed by gonadal followed by phenotypic sex in mammals	Alfred Jost (1940s and 1950s)
Male reproduction endocrine theory	The role of endocrine hormones in male reproduction integrating the testis, brain and other reproductive organs	Berthold 1879; Alfred Jost (1940s and 1950s); Mc Cullagh (1930s and 1940s)

of the genital tract in mammals. Aristotle also developed early theories or speculations on the role of the testis in male biology (Hippocrates, 1962). Over the next 1000 years debates and theories on the impacts of the testis on male biology developed ranging from the impact of temperature on the testis to the effects of the testis on the heart, brain, and muscle development (Diamandopoulos et al., 2005). One of the more interesting speculations was the role of a testis derived liquid on the males biology (Diamandopoulos et al., 2005; Galen, 1964). Although the majority of these theories and speculations were neither accurate or based on specific observations, Aristotle's concepts had significant impacts for centuries on our approach and progress of scientific advances (Table 1).

The use of castrations in ancient societies in humans to create eunuchs was reported in Assyrian, Egyptian, and Greek cultures. Observations of the physiological impacts of castration were documented in all these societies. This included infertility, brain behavioral effects, voice changes, weight, and metabolism alterations and more. These observations led to a variety of early theories and speculations. A prominent link between the testis and the brain was discussed by Aristotle and others throughout history, which was the first speculations of the brain and gonadal axis today known to be endocrine based. Although these early speculations and theories were not completely accurate, they laid the foundation for much of the early male reproduction research in the last century.

Reproduction and Sperm Theory

One of the first recorded reproduction theories or speculations was proposed by Aristotle (Table 1). Observations with castration and role of the testis to create semen Aristotle proposed the male provided the seed having an active role in reproduction and the female provided the soil having a passive role in reproduction. Although this reproduction theory was based on observations at the time, this Aristotle concept persisted for nearly 2000 years and impacted the majority of reproductive biology research and society. A classic example involving one of the first observations following the development of the single lens microscope in the 1600s by Leewenhock (1678) was made on his own sperm which lead him to describe the presence and vigor of "animalcules," the name that he gave to spermatozoa. Under the name of "homunculus" the speculation was made by Hartsoeker (1694) that the spermatozoon contained the entire preformed human (homunculus)/animal (animalcules) with a number of supporting microscopic observations (Hartsoeker, 1696). The concept named "animalculism" was that the sperm provided the seed that contained the preformed animal (Fig. 1) and that the female provided the soil to allow its growth. Therefore, Aristotle's reproduction theory was supported.

This preformation sperm theory was debated for the next 100 years. The work of the Reverent Lazzaro Spallanzani (1717, 1780) lead to the description of the mobility of spermatozoa (the "small worms" as he wrote) and he also provided the first artificial insemination using a dog (Inza, 1964). Although all of Spallanzani's work supported the role of the sperm in reproduction, he believed in ovism and the role of a preformed person in the egg. The very long standing controversy about the role of spermatozoa in reproduction really ended with Prevost and Dumas in 1824 who rediscovered after Spallanzani the relationship between the male gamete and reproductive abilities. The named "spermatozoa" was first coined by Van Baer soon after (1827), and it was van Kolliker in 1841 who introduced the fact that spermatozoa derive from germ cells in the testis.

During the same period, it was William Harvey (1578–1657), who discovered circulation of blood, but he also studied the ovary anatomy making major observations on the histology of the ovary and anatomy of the female reproductive system. Observations led Harvey to the proposal that ovulation and the ovary had a critical role in reproduction (Harvey, 1651). Harvey did not discover the egg as during the same period Bishop Niels Stensen (1638–86) using fish ovaries to discover the egg and later using the mule, horse and donkey described the role of the egg in reproduction (Volker, 1989). The debate that the female and egg played an active role in reproduction was contested during the 1600s and 1700s period due in part to the predominant influence of the early Aristotle concepts. The active role of the female in reproduction slowly became accepted, however, this provides an example of how early scientific theories can develop into dogma and paradigms that can persist and sometimes impair the progression of science.

Male Reproductive Tract Organ and Anatomy

Anatomy was one of the first biological fields to develop and was documented by artists and scientists from early Egyptian, Greek, and Roman periods through the modern era. All those societies had documentation of testis and ovary which suggested their

Fig. 1 Homunculus involving preformed human/animal in the head of the sperm to then allow growth in the female From Hartsoeker, N. *Principes de Physique*. Paris, 1696.

understanding of the link with reproduction. Later artists such as Leonardo Di Vinci (1452–1519) created drawings of reproductive systems and organs such as the male reproductive tract. This included an anatomical representation of coitus of a hemisected man and woman, and is best known for his analysis of fetal developmental anatomy (O'Malley, 2003). Many artists and scientists documented the anatomy of many reproductive organs, such as the work of Vesale in 1513, but one of the most influential and informative scientists was Regneri de Graaf in the 1600s (de Graaf, 1677). The most complete and insightful male and female reproductive tract anatomy was provided by de Graaf and detailed the specific organs, connections and hypothetical functions. An example of his detailed drawings of male reproductive tract anatomy is presented in Figs. 2 and 3. In addition to the testis, rete testis and epididymis, seminal vesical, vas deferens and penis are presented in detail (de Graaf, 1677). The work of early anatomists such as de Graaf set the ground work for our modern understanding of male reproduction. The development of the microscope in the late 1600s allowed more detailed anatomy and histology to be performed of male reproductive tract tissues. This analysis advanced the concepts of the "Cell Theory" which suggested tissues and organs had specific cells that allowed them to function. One of the first tissues studied was the testis due to its importance for reproduction and having more understanding than most tissues. Following the understanding sperm was produced within the seminiferous tubules, the first

Testis and Epididymis Anatomy (De Graaf, 1677) (10)

somatic cell identified at this level was the Sertoli cell. Enrico Sertoli was an Italian physician that used the early microscope to describe the structure and histology of this critical cell type. Sertoli elaborated the crucial concept that Sertoli cells are the “nurse cells” of germ cells (Anon, 1987). His early diagrams of these cells that now have his name are shown in Fig. 4 (Sertoli, 1865). The various structures of the Sertoli cell and its role in the development of the seminiferous tubule are described from this 1865 observation (Sertoli, 1865). This is simply the first of many different observations by many scientists to describe specific cell types in various male reproduction tract organs. Clearly the organ anatomy and cellular histology of the 1600s–1800s help establish the initial building blocks for current reproduction research.

Early Sex Determination Theory

The origins of males versus females through the process of sex determination was also considered in early societies, but the first documented theory or speculation was provided by Aristotle (Table 1). The concept was that environment promoted sex determination and Aristotle suggested heat initiated male development and cold initiated female development (Fig. 4). Although this does exist in some organisms such as turtles, this is now known not to be a factor in mammals and most organisms. This theory has persisted even into the modern era. An example is in the 1980s when the prince of England was about to have a child the fact he had been a helicopter pilot was determined by the popular press to indicate he would have a male child. Therefore, even today the concept environment can impact sex determination persists from these early Aristotle concepts.

This environmental impact on sex determination persisted until the mid-1900s. The first modern theory of sex determination was provided by Alfred Jost, University of Paris in the 1940s and 1950s (Jost, 1945, 1970). The development of genetics in the early 1900s led to the identification of sex chromosomes that then through experiments by Jost on early fetal sex determination led to his

Sertoli Cell Structure (E. Sertoli, 1865) (12)

Fig. 4 Aristotle sex determination theory. The relative preponderances of the four elements and their qualities in males and females. The greater innate heat of the male allows for a greater degree of concoction of the nourishment and hence a more concentrated white semen is formed. From Sertoli E. (1865). Dell'esistenza di particolari cellule ramificate nei canalicoli seminiferi del testicolo umano. Morgagni 7, 31–40.

theory for sex determination ([Table 1](#)). This involved the theory that genetic sex (sex chromosomes) promote gonadal sex (testis or ovary) that then promotes phenotypic sex (male or female) ([Jost, 1945, 1970](#)), [Fig. 5](#). This sex determination theory displaced the early Aristotle concept of environmental sex determination, but surprisingly Aristotle's theory was predominant for nearly 2000 years. Another example of how early historic concepts can impede the progression of science by development of strong dogma or paradigms.

Early Endocrine Observations

The development of early anatomy and cell histology in the 1600s and 1700s established an understanding of the complexities of male reproduction in a number of different species. The first major advance to the next level was made by Claude Bernard in the 1850s with the advent of the field of physiology. He is considered the father of the field through his insight and experiments that different organ systems interact to influence their functions. He described the concept of cybernetic systems between organs and tissues through the internal milieu as the basis of how the organism functions ([De La, 1872](#)). Although he did not focus on

Fig. 5 Jost sex determination theory. Role of genetic sex (sex chromosomes) in promoting gonadal sex (testis or ovary) that promote male or female phenotypic sex characteristics (Jost, 1945).

reproduction, the concepts and theory initiated the fields of physiology, endocrinology and cell biology. One of the systems he did consider was the brain-gonadal interaction. Therefore, Bernard set the ground work for reproduction physiology and indirectly led to the field of endocrinology.

With this in mind and the summary of the main milestones concerning the testis itself, the seminiferous tubules and spermatozoa (see above) it is interesting to note that the first demonstration of the role of a “gland,” was provided by Berthold in 1849 when he showed that while castration was followed by regression of the cockscomb, transplantation of the testes to the castrated cocks restored its size. Very soon afterward Leydig (1850) provided the first microscopic description of the interstitial cells of the testis which were named the Leydig cells and are now known to produce the hormones named androgens, and Insulin-like factor 3 the latter being responsible for testicular descent in mammals.

The early 1900s involved a large number of physiology experiments to examine how organ systems influence each other and identified substances that mediate those interactions. Some of the first hormones identified were shown to be produced by the gonads and impact a wide variety of tissues (Table 1). This involved the identification of testosterone being produced by the testis (McCullagh, 1948). In addition, one of the first protein hormones inhibin being produced by the testis and impacting the brain hypothalamus (McCullagh, 1948). One of the prominent scientists involved was (McCullagh, 1948). This initiated in the following decades an increasing number of endocrine focused experiments to help understand male reproduction. Another example is related to the work of Alfred Jost, Fig. 6, who during his work on sex determination identified a testis determining factor that we now know is a specific gene (SRY), as well as a hormone anti-Müllerian hormone (AMH) which is critical in both male and female fetal sex determination and in the adult (Jost, 1945, 1970). Over the past 100 years the advances have been far more rapid than in previous centuries.

Summary

The review of ancient and early history has revealed that early history concepts for science are often not completely accurate, but they do have an important role in the progression of science. The advantage is that a theory is developed that can be tested through experiment and during that process new observations can be made to progress science. The disadvantage is that the theory developed can turn into dogma and a strong paradigm that becomes so ingrained that it can impede the progression of science. In considering the history and concepts of male reproduction, there have been good examples of both. Although the insight and

Fig. 6 Sex determination theory. From Jost, A. (1970). Hormonal factors in the sex differentiation of the mammalian foetus. *Philosophical transactions of the Royal Society of London Series B, Biological sciences* **259**(828), 119–130; Jost, A. (1945). Sur l'action de divers androgenes dans la differentiation embryonnaire du sexe. *Comptes Rendus des Seances de la Societe de Biologie et de Ses Filiales* **139**, 670–672.

theories of Aristotle were surprising, the development of dogma around these concepts clearly impeded the progression of science in subsequent centuries. We have displaced many of these concepts, but even today we have our paradigms. The future will need to assess these paradigms and not resist the paradigm shifts required to advance science.

Considering the male reproduction historic concepts can assist in our understanding of the origins of current science and theories. Perhaps the biggest value of this historic understanding is to put the current activities in perspective, which will only help the advances of male reproductive sciences in the future.

Development of Testes

The testes are located in the scrotum since sperm production requires a temperature that is cooler than that of the abdomen (de Kretser, 2016). They develop in the embryo just distal to the kidneys and descend into the scrotum shortly after birth through the inguinal canal. This canal, found on both sides in the region of the groin, is formed by the attachments of one of the muscles of the abdominal wall. The canal extends downwards and medially in the groin and links the abdominal cavity with the scrotum (de Kretser, 2016; de Kretser et al., 1982; Clermont and Huckins, 1961; Roosen-Runge and Holstein, 1978; Hutson et al., 1990).

Descent of the Testes

In some males, the inguinal canal does not close and the testes may retract from the scrotum into the abdominal cavity for brief periods. The descent of the testis is important because the temperature of the scrotum is lower than the intra-abdominal temperature and the germ cells require a lower temperature for their survival (Hutson et al., 1992). In some males, the inguinal canal which normally closes after the testes descend, remains patent and the testes may retract for varying periods causing damage to the germ cells because of the higher intra-abdominal temperature. Descent of the testis begins in the fetus at about 28 weeks of gestation and should be complete by birth and it is controlled by a Leydig cell secreted protein called insulin-like protein 3 which is a member of the insulin-like protein super family (de Kretser et al., 1982; Bowles and Koopman, 2007).

Failure of the testes to descend should be diagnosed as soon possible as spermatogenic damage and infertility may result. Surgery can be undertaken to close off the inguinal canal so that the testes are permanently located in the scrotum. The testes are ovoid in shape and in adults, their volume ranges from 15 to 35 mL. At birth they are about 1–3 mL in volume grow rapidly during pubertal development. The availability of an orchidometer, a range of spheres from 1 to 3 mL in progressively increasing volumes to 35 mL, is every helpful in determining testicular size (Fig. 1).

Fig. 1 *Orchidometer*. This set of models of differing testicular size helps the physician in assessing the size of the testes in patients with delayed puberty, infertility or potential testicular tumors.

Fig. 2 The anatomical features of the testis, epididymis, vas deferens and the pampiniform plexus of veins, that surround the testicular artery, represent the venous drainage of the testis and epididymis.

The testes are covered by thick fibrous tissue that forms the tunica albuginea and should be smooth on their anterior and lateral surfaces. These surfaces are also covered by a serous membrane called the tunica vaginalis. Posteriorly, in the region under the epididymis, the tunica albuginea is thickened and projects into the parenchyma of the testes to form the mediastinum of the testes. A series of tubules traverse the mediastinum of the testis to link the seminiferous tubules to the efferent ducts that form the head of the epididymis (Roosen-Runge and Holstein, 1978) (Fig. 2).

In prepubertal boys, the germ cells in the testes are called gonocytes which are centrally placed in the seminiferous cords, that are the precursors of the seminiferous tubules. The other cellular components of the cords are the immature Sertoli cells that extend from the basement membrane of the tubule to the lumen of the seminiferous tubules. As development proceeds, the gonocytes move to the periphery of the cords to lie on the basement membrane of the cords and commence dividing by mitosis to give rise to the spermatogonial stem cells a process that requires retinoic acid and Oct 4 (de Rooij and Russell, 2000; de Rooij and Grootegeed, 1998; Dann et al., 2008; Bowles and Koopman, 2007). Continuation of spermatogonial mitosis requires the action of Foxo1 and the spermatogonial stem cells have the capacity for pluripotency, a characteristic marker of stem cells in many tissues (de Rooij and Russell, 2000; de Rooij, 2001; Goertz et al., 2011). When this occurs at the time of puberty, the basally placed Sertoli cells form specialized tight junctions just central to the gonocytes thereby preventing inter-cellular transport of substances and creating a blood–testis barrier (Dann et al., 2008). External to the basement membrane of the seminiferous tubules, there is a layer of myofibroblasts that can contract and increase the intra-tubular pressure. This facilitates the movement of sperm and the fluid produced by the Sertoli cells in to the rete testis (Simoni et al., 1999).

Functions

The testes have three functions, the production of sperm, the secretion of the steroid hormone, testosterone, after puberty and the production and secretion of protein hormones inhibin, activin, and follistatin. In addition, insulin and IGF1 are important in the control of Sertoli cell proliferation (Pitetti et al., 2013). Testosterone is synthesized and secreted by the Leydig cells of the testis that lie close to blood vessels found in the inter-tubular region of the testis. The Leydig cells have the characteristics of steroid secreting cells, namely a well developed smooth endoplasmic reticulum and mitochondria which have tubular cristae unlike “conventional” mitochondria in which the inner mitochondrial membrane forms “plate-like” cristae (de Kretser, 1967).

There are also lymphatic vessels in the inter-tubular compartment of the testes and these join abdominal lymphatics that also transport testosterone into the chest where they join the thoracic duct, the common duct of all lymphatic vessels in the body. The thoracic duct joins the venous system at the junction of the left subclavian vein and the left internal jugular vein (Stanton, 2016) (Fig. 2).

Spermatogenesis

The testes produce sperm in tubules termed seminiferous tubules by a process called spermatogenesis. These tubules are composed of germ cells and the supporting network of Sertoli cells. The tubules are surrounded by a layer of basement membrane, external to which lies a plate-like layer of peritubular cells which are contractile effectively “squeezing” the seminiferous tubules (Holstein et al., 1996; Simoni et al., 1999). Thereby they assist in moving sperm, released into the lumen of the seminiferous tubules, toward an irregular network of tubules located at the posterior and superior pole of the testis called the rete testis.

The rete testis is connected with the duct of the epididymis, a coiled tube that lies at the posterior aspect of the testis and is divided into the head, body and tail, the latter continuing as the vas deferens (Johnston and Whillis, 1954). In the epididymis, the sperm, which are still not motile, are moved by muscular contractions from the head to the tail of the epididymis. They acquire mobility as they pass through the epididymis to enter the vas deferens (Baker, 1989). The latter delivers the sperm during ejaculation to enter the prostatic urethra and pass through the penile urethra.

The cellular components in the seminiferous tubules are the germ cells that are the precursors of sperm and also the Sertoli cells. The latter are named after the person who first described them and they are a critical component of the seminiferous epithelium. They extend from the basement membrane of the tubule to the lumen and send projections between the surrounding germ cells not unlike the branches of a tree from the trunk. These projections contain microfilaments that provide a structural framework for the epithelium given that the germ cell components migrate from the basally placed spermatogonia to the centrally placed spermatids and their final product, the spermatozoa (Fig. 3).

In prepubertal boys, the germ cells in the testes are called gonocytes and they are centrally placed in the seminiferous cords that comprise the testis (Clermont and Huckins, 1961; de Rooij and Grootegoed, 1998; de Rooij and Russell, 2000). The other cells comprising the cords are the immature Sertoli cells that extend from the basement membrane of the cords surrounding the gonocytes. At the commencement of puberty, the gonocytes move to the periphery of the cords and the Sertoli cells form specialized cell junctions central to the gonocytes which will progress to give rise to the population of spermatogonia, the precursors to the subsequent stages of spermatogenesis (Johnston and Whillis, 1954). These changes, under the influence of the pubertal increase in FSH, act through Foxo1 and Oct 4 (Dann et al., 2008).

Where adjacent Sertoli cell projections meet basally, they form specialized tight cell junctions that prevent inter-cellular transport creating a blood–testis barrier (Dym and Fawcett, 1970; Russell, 1977). These tight junctions are placed at such a position in the seminiferous epithelium that only the spermatogonia are in contact with the basement membrane of the seminiferous tubules. All other germ cells lie central to the blood–testis barrier and are thus dependent on the Sertoli cells for transport of materials for optimal germ cell function and can be considered to “nurse” germ cells central to these inter-Sertoli cell junctions.

The inter-Sertoli cell junctions must open centrally to enable the progeny of spermatogonia, the primary spermatocytes, to leave the basal compartment and enter the luminal compartment. The inter-Sertoli cell junctions reform basally below the primary spermatocytes that now lie within adluminal compartment of the seminiferous tubule (Stanton, 2016).

Studies have shown that the number of Sertoli cells can affect the magnitude of sperm production. One of the important factors that controls Sertoli cell numbers is activin A which stimulates proliferation and inhibits differentiation of Sertoli cells (Baker, 1989; Kreuger et al., 1974). Increasing systemic levels of activin A using an adeno-associated virus expressing activin A (Russell, 1977) stimulated proliferation and prevented differentiation of Sertoli cells in mice. This was associated with disruption of the blood testis barrier formed by the inter-Sertoli cell junctions and resulted in a 23.5% decrease in testis weight due to diminished spermatogenesis linked to disordered Sertoli cell function. The latter was associated with increase in markers of juvenile Sertoli cells and a decrease in claudin-11, a marker of mature Sertoli cells. These data are consistent with studies of the levels of activin A in mice during normal post-natal development which established that activin A levels are elevated at birth but decline rapidly after day 4 postpartum (Meehan et al., 2000).

Other studies using treatment with FSH or thyroxine, a hormone secreted by the thyroid gland, can enhance Sertoli cell proliferation and thus increase sperm output.

In part, the action of FSH on spermatogenesis is exerted directly via spermatogonia which are the only germ cells that have FSH receptors (Simoni et al., 1999). Germ cells also do not have androgen receptors and thus the requirement of testosterone for successful spermatogenesis is dependent on the presence of androgen receptors on the Sertoli cells.

Since in the human, testicular sperm production continues from puberty throughout life, there is clearly a need for a population of stem cells to produce the precursor cells that develop into sperm. The cells forming this stem cell population are the spermatogonia that undergo several mitotic divisions and have 46 chromosomes as do all other cells in organs throughout the body (Amory et al., 2011). They develop from the gonocyte population found in the testes of prepubertal boys. The gonocytes are initially placed in the centre of the seminiferous cords and migrate to lie between the precursors of the Sertoli cells and, as with the gonocytes, the spermatogonia are basally placed in contact with the basement membrane of the seminiferous tubules. These cells undergo several stages of development and are designated by their cytological features before commencing meiosis.

Fig. 3 The efferent ducts draining from the rete testis to form the head of the epididymis is illustrated together with the distal regions of the epididymis termed the body and tail.

The spermatogonia lose their contact with the basement membrane of the tubule when they begin another process of cell division called meiosis by which the chromosome numbers in these cells are reduced from 46 to 23. These cells are called primary spermatocytes.

During meiosis, the homologous chromosomes, derived originally from the fertilization of the egg, one provided by the mother, and the other member of the pair, provided by the father via his sperm, pair and replicate their DNA (deoxyribonucleic acid). The primary spermatocytes thus have nuclear features which enable the identification of the stages as the cells undergo the first meiotic division during which, one of each homologous chromosome pair, moves to the opposite pole of the cell. These cell types are named by the stage of meiosis that they have reached and can be identified by the chromatin pattern in their nucleus associated with the chromosome replication. Leptotene, zygotene, pachytene, diplotene, and diakinesis stages can be identified and, unlike cell division in somatic cells, these germ cells remain connected by intercellular bridges that link the cytoplasm of these cells. These bridges enable the development of the “chains” of germ cells and remain in place in the primary and secondary spermatocyte populations. This process requires the involvement of retinoic acid and androgens to proceed to completion. (Amory et al., 2011).

The completion the first meiotic division gives rise to cells called secondary spermatocytes that have half the number of chromosomes, 23, termed the haploid number, in contrast to their diploid precursor which had 46. The secondary spermatocytes then divide by mitosis to give rise to a further population of cells called round spermatids that are still connected by the cytoplasmic bridges.

Spermiogenesis

The round spermatids do not divide further but are transformed by a complex series of changes into a sperm, the process being called spermiogenesis (de Kretser, 1969). The basic changes in the developing spermatids during spermiogenesis are common to many mammalian species but the resulting sperm vary in their morphology especially in the shape of the head of the resulting sperm. The structure of the sperm tail however has many features in common across species. In the round spermatids the nucleus, which is centrally placed in the cell, is “capped” at one pole by a series of vesicles from the Golgi complex that coalesce to form a “cap” that is called the acrosome and is applied to that part of the nucleus closest to the acrosome. The acrosome covers approximately 30%–50% of the nuclear surface.

The nucleus, in the region of the acrosome, comes into close apposition with the cell membrane but remains separated from the nucleus by the acrosome.

Subsequently, as spermatid development continues, the nuclear chromatin undergoes a progressive condensation forming electron dense granules associated with stabilization of the DNA (Sassone-Corsi, 2002). That process involves the replacement of lysine-rich histones with transitional proteins, subsequently replaced by arginine-rich proteins called protamines. The nuclear chromatin granules condense as spermiogenesis progresses and it becomes more difficult to identify individual granules (Fig. 4).

At the pole of the nucleus opposite to the acrosome, a pair of centrioles, that participate in the development of the flagellum, lodge in a small fossa or indentation that still lies external to the nuclear membrane. This whole complex is called the connecting piece. The centriole closest to the nucleus, called the proximal centriole, lies at right angles to the plane of the distal centriole which gives rise to the core of the sperm tail called the axoneme. The axoneme is composed of a core of microtubules which forms the basis of the sperm tail sometimes called the axial filament (Fawcett, 1975).

The axial filament comprises nine pairs of doublet microtubules which surround two centrally placed single microtubules, a structure that is identical to the structure of cilia which also exhibit motility similar to the sperm tail.

A second set of nine outer dense fibers surround the axial filament distal to a dense ring termed the annulus. The annulus marks the distal end of the mid-piece and its mitochondrial sheath and defines the commencement of the fibrous sheath. The annulus marks the commencement of the region of the sperm tail called the principal-piece and the axonemal core, distal to the termination of the fibrous sheath, is termed the end-piece.

The final step, before sperm are released from the epithelium by a process called spermiation, is a movement of mitochondria, that up to this point have been distributed around the periphery of the spermatid cell membrane, to surround the mid-piece to form a “mitochondrial sheath” distal to the connecting-piece and ending at the annulus.

Spermiation, involves the release of sperm from the seminiferous epithelium. At this stage, the cytoplasm of the spermatid has migrated to a caudal position around the tail. Projections of Sertoli cells invaginate this caudal cytoplasmic collection to “literally” pull the residual cytoplasm off the spermatid, thereby releasing it into the lumen of the seminiferous tubule.

The residual bodies within the Sertoli cells, that contain the “unwanted” cellular components of the spermatids, are moved toward the base of the Sertoli cells and progressively “digested” by lysosomes. There is some data to suggest that these cellular components signal to the Sertoli cell that a “generation” of sperm have been released from that region of the epithelium.

The spermatozoa, that are released from the Sertoli cells are still immotile. They, together with fluid secreted by the Sertoli cells into the lumen of the seminiferous tubules, are moved toward the rete testis by the contractions of the peritubular myoid cells and enter the epididymis.

Fig. 4 The specific stages of spermiogenesis, the process by which a round spermatid (Sa) is transformed into a spermatozoon (Sd2) are illustrated. Reproduced with permission from de Kretser, D.M. (1969). Ultrastructural features of human spermiogenesis. *Zeitschrift für Zellforschung* **98**, 477–505.

Glossary

DHT 5 Alpha-dihydrotestosterone.

GABA Gamma-aminobutyric acid.

GnRH Gonadotropin releasing hormone.

HPT Hypothalamic-pituitary-testis.

KISS1R Kisspeptin receptor 1 (previously known as GPR54).

KNDy Kisspeptin/neurokinin B/dynorphin.

Introduction

The hypothalamic-pituitary-testis axis (HPT axis) regulates function of the testis that is comprised of two main components: synthesis of testosterone and production of sperm in the male at various stages of life. Disorders of the testes or HPT axis may result in abnormal development, including ambiguous genitalia in infancy; failure to develop male sexual characteristics at puberty; and hypogonadism and infertility in adults. This article intends to provide a brief overview of the endocrinology of the male reproductive system including the HPT axis, testosterone biosynthesis, effects of testosterone, and aberrations in testosterone secretion and action. Spermatogenesis will also be discussed in brief.

Regulation of Steroidogenesis—HPT Axis

Anatomy

The hypothalamus sits at the base of the third ventricle of the brain; it has a specialized vascular system. The superior hypophyseal arteries branch from the internal carotid artery form the primary capillary plexus that carries blood to the median eminence. The blood is drained from the median eminence via the hypophyseal portal veins into the secondary venous plexus, which supplies the anterior pituitary gland.

The hypothalamus is divided into three zones: the lateral zone, medial zone, and periventricular zone. These zones are further subdivided into regions, and each region contains distinct nuclei (Crosby and Woodburne, 1940). Kisspeptin neurons can be found in the infundibular nucleus in humans (homologous to the arcuate nucleus of rodents), as well as the rostral preoptic area. In rodents, the kisspeptin neurons in the rostral area are located in the anteroventral periventricular nucleus and periventricular nucleus, whereas in humans, the kisspeptin neurons are scattered within the preoptic region. The neurons that release gonadotropin-releasing hormone (GnRH) are found from the preoptic area to the infundibular nucleus (Skorupskaitė et al., 2014).

The neurons that produce GnRH extend axons from the preoptic region to the median eminence at the base of the brain. The axon terminals release GnRH into the primary plexus capillaries, which then flows to the anterior pituitary via the hypophyseal portal system. The anterior pituitary contains the gonadotrophs that secrete luteinizing hormone (LH) and follicle stimulating hormone (FSH). LH and FSH circulate in the systemic arterial system to act on the Leydig cells and Sertoli cells in the testes.

The Leydig cells in the interstitium of the testes are responsible for producing sex steroids. The Sertoli cells within the seminiferous tubules are embedded in the germinal epithelium; they form the blood-testis barrier and are involved in the initiation and maintenance of spermatogenesis. They also produce sex hormone binding globulin (SHBG), anti-müllerian hormone, activin A, inhibin B, and other factors (Fig. 1).

Secretion of GnRH

GnRH is secreted in pulses by the GnRH neurons in the hypothalamus. Secretion surges in infancy producing an increase in LH secretion (mini-puberty in boys). There is another surge in puberty, again with increased LH secretion. Higher frequency GnRH pulses preferentially stimulate LH release, whereas lower frequency pulses preferentially stimulates FSH release (Thompson and Kaiser, 2014).

The GnRH neurons receive many excitatory and inhibitory signals from neuromodulators. Kisspeptin/neurokinin B/dynorphin (KNDy) neurons and kisspeptin neurons in the hypothalamus synchronize GnRH release (Fig. 2) (Pinilla et al., 2012). Kisspeptin acts directly on GnRH neurons to enhance GnRH secretion, via activation of phospholipase C, which affects calcium release and

Fig. 1 Hypothalamic—Pituitary—Testis showing the negative feedback of the sex steroids on the hypothalamus and pituitary. Adapted with permission from Center for Male Reproductive Medicine and Microsurgery—Cornell, and Gray's Anatomy Plates from public domain.

activates protein kinase C. Kisspeptin and GnRH neurons have axo-somatic, axo-dendritic, and axo-axonal connections. The KNDy neurons are inter-connected into a neuronal network. Inside the KNDy neuronal network, neurokinin B (a tachykinin) initiates each GnRH pulse and dynorphin inhibits KNDy neural activity to terminate each pulse (Skorupskaitė et al., 2014).

Kisspeptin and its G-protein coupled receptor KISS1R (previously known as GPR54) are involved in the onset and progression of puberty. During puberty, kisspeptin secretion increases, and kisspeptin pulse frequency increases. Puberty can be postponed with administration of a kisspeptin antagonist. Mutations in kisspeptin or Kiss1R can lead to delayed or absent puberty and hypogonadotropic hypogonadism, or precocious puberty, depending on the type of mutation. Similarly, inactivating mutations of neurokinin B also cause hypogonadotropic hypogonadism (Skorupskaitė et al., 2014; Terasawa et al., 2013).

Other neurotransmitters, including glutamate and GABA, also have an effect on GnRH secretion. GABA has an inhibitory effect on GnRH prior to puberty, and during pubertal onset, GABAergic inhibition is reduced (Terasawa et al., 2013).

Multiple factors affect kisspeptin expression, including testosterone and progestogens, metabolic factors, and medications. KNDy neurons have ER alpha, progesterone, and androgen receptors. Importantly, GnRH neurons do not express androgen receptors or estrogen receptors, thus androgens and estrogens must act on other cells that affect GnRH secretion. KNDy neurons are an integral part of the mechanism by which sex steroids inhibit GnRH release. In the infundibular nucleus, estrogen and testosterone suppresses the secretion of kisspeptin and neurokinin B and stimulates the secretion of dynorphin, leading to decreased secretion of GnRH (Skorupskaitė et al., 2014). In women, during the late follicular phase there is also estrogen positive feedback to the kisspeptin neurons to induce the GnRH/LH surge during ovulation (Fig. 2). The mechanism behind the positive estrogen feedback is species specific.

Fig. 2 Regulation of GnRH secretion by Kisspeptin and KNDy neuron. Modified from Roa J, Tena-Sempere M. (2010). Energy balance and puberty onset: Emerging role of central mTOR signaling. *Trends in Endocrinology and Metabolism* 21(9):519–528.

Environmental factors also affect kisspeptin expression. Stress increases corticotropin-releasing hormone, which inhibits GnRH release. Nutritional status affects leptin levels, and both caloric restriction and obesity cause hypogonadotropic hypogonadism. Leptin receptors are present on kisspeptin neurons, and in the setting of caloric restriction, leptin levels fall leading to a decrease in kisspeptin. Exogenous kisspeptin administration has been shown to improve the low gonadotropin levels and estrogen levels of malnourished rats (Castellano et al., 2005). Medications such as opioids inhibit GnRH release via the KNDy neurons, decreasing LH more strongly than FSH. There have been numerous studies on opioid-induced endocrinopathy, of which hypogonadism is one aspect.

FSH, LH, and the Testes

GnRH stimulates secretion of the gonadotropins LH and FSH. LH and FSH are two of four glycoprotein hormones that have identical alpha subunits but different beta subunits; the other two members of the family are TSH and hCG. Due to the differences in glycosylation, the half-life of LH is approximately 20 min, whereas the half-life of FSH is approximately 3–4 h (Fry et al., 1987).

FSH stimulates Sertoli cells to increase production of proteins including androgen binding protein, anti-Müllerian hormone, and inhibin B. It also increases the responsiveness of the Sertoli cell to testosterone, via effects on the androgen receptor. FSH receptors in men are only found in the testis, primarily on the Sertoli cells. Androgen binding protein (ABP) in rats is similar to SHBG in humans. They are glycoproteins with the same amino acid sequence but different sugar moieties. ABP does not appear in the rodent circulation, where in the human SHBG is secreted by the liver and binds circulating testosterone and estradiol. ABP binds to testosterone to create high levels of testosterone within the seminiferous tubules which is essential for spermatogenesis. Inhibin B inhibits FSH secretion at the level of the pituitary gland; it does not affect the hypothalamus. Activin A is another paracrine regulator of spermatogenesis and a stimulator of FSH secretion at the level of the pituitary gland. Anti-Müllerian hormone (AMH) is important during embryogenic regulation of sexual differentiation.

LH binds to the luteinizing hormone/chorionic gonadotropin (LH/CG) receptor on Leydig cells in the testis. This leads to increase in protein kinase A levels in the cell, upregulation of the steroidogenic acute regulatory protein (StAR) and other protein complexes. This will be discussed in detail on the section on testicular steroidogenesis.

In the testis, testosterone has paracrine effects; testosterone, along with FSH, stimulates initiation and maintenance of spermatogenesis. Testosterone has systemic effects, both as testosterone and via conversion to dihydrotestosterone (DHT) and estradiol (E2). Testosterone and its metabolites are part of a negative feedback loop at the level of the pituitary and the hypothalamus. In the central nervous system, aromatase converts testosterone into estradiol. As mentioned previously, testosterone and estradiol suppress GnRH release at the level of the hypothalamus, in part through suppression of KNDy neurons which leads to inhibition of GnRH release (Skorupskaite et al., 2014) (Fig. 2). Sex steroids also affect FSH and LH secretion at the level of the pituitary gland (Fig. 1). Testosterone has some direct effects on the gonadotrophs in the anterior pituitary, but its main effect is via intra-pituitary conversion to estradiol. Together, estradiol and testosterone make the anterior pituitary less responsive to GnRH by decreasing GnRH receptor binding (Bagatell et al., 1994; Heber et al., 1982).

Spermatogenesis

Spermatogenesis is tightly linked to the endocrinology of the testis. Spermatogenesis begins in the seminiferous tubules of the testes. As mentioned above, the Sertoli cells are stimulated by FSH and high testosterone concentrations within the testes. In men there are three types of spermatogonia: types Ad, Ap, and B. Some of the stem cells (Ad) are kept in reserve and rarely divide, whereas other stem cells (Ap) are actively dividing. These actively dividing spermatogonia may become Ap spermatogonia again, in a process of self-renewal, or they may become type B spermatogonia (diploid, 2n), which divide and differentiate to become primary spermatocytes (diploid, 4n) via mitosis. Each primary spermatocyte divides into two secondary spermatocytes (2n), via meiosis I. The secondary spermatocytes each divide via meiosis II again, forming four spermatids (1n) per primary spermatocyte. The spermatids then undergo changes in shape and structure in a process called spermiogenesis. Without testosterone or without FSH, spermatogenesis cannot be completed (Zirkin et al., 1989).

Gonadal Androgens

Testicular Steroidogenesis

Testosterone is the main androgen produced by the testes. Cholesterol is transported from the outer mitochondrial membrane to the inner mitochondrial membrane by a complex of proteins including the steroidogenic acute regulatory protein (StAR) (Stocco et al., 2017), Translocator Protein (TSPO) (Papadopoulos et al., 2015) and voltage-dependent anion channel amongst others. In the adrenals, and to a smaller extent in the testes, liver, and brain, cholesterol is converted to pregnenolone via CYP11A (also known as cholesterol side-chain cleavage enzyme or P450_{sc}) located in the inner mitochondrial membrane (Miller, 1988). Pregnenolone is converted to androstenedione via CYP17A1 (17 α hydroxylase/17,20 lyase) and 3 β -HSD (delta 5–4 isomerase), via the delta-5 pathway and the delta-4 pathway. Androstenedione is converted to testosterone by 17 β -hydroxysteroid dehydrogenase (17 β -HSD). For a more detailed description, see Chapter Leydig Cell Androgen Synthesis (Fig. 3).

In men, over 90%–95% of testosterone comes from the testes, and the remaining testosterone is produced by the adrenal glands or from extraglandular conversion of dehydroepiandrosterone (DHEA) and androstenedione. A small amount of the testosterone produced in the testes is converted to estradiol via aromatase. The testes are a minor direct secretory source of circulating estradiol; however, the majority of the estradiol produced in men is from peripheral conversion of testosterone to estradiol (Raven et al., 2006). Examples of tissues with high levels of aromatase are adipose tissue, skin, bone, brain, pituitary, testis, liver, intestine, and breast stromal cells. Estradiol is important for skeletal growth during puberty, and high estradiol levels at the end of puberty causes fusion of the epiphyseal plates. Estradiol is important for maintaining bone health and estrogen deficiency leads to osteoporosis in men. Estradiol is also important in the regulation of the hypothalamic-pituitary-gonadal axis as described above.

Testosterone is also converted to dihydrotestosterone (DHT) via 5-alpha reductase. DHT is 3–5 times as potent as testosterone in some tissues. DHT has a higher affinity for the androgen receptor, and dissociates from the receptor about three times more slowly. Examples of tissues with high levels of 5-alpha reductase are the prostate, seminal vesicles, epididymis, liver, brain, skin, and hair follicles. The serum levels of DHT are much lower than the serum levels of testosterone, but in tissues such as the prostate, the local levels of DHT are 5–10 $\times$ higher than the level of testosterone (Swerdlhoff et al., 2017). DHT is not converted to an estrogen with aromatase, and thus does not have estrogenic effects (Liao et al., 1973).

Approximately 45% of serum testosterone in men is bound to SHBG, 50%–60% is bound to albumin, and 2% is free. Testosterone binds more strongly to SHBG than to albumin. Bioavailable testosterone includes albumin-bound testosterone plus free testosterone (Emadi-Konjin et al., 2003). According to the free hormone hypothesis, the “intracellular hormone concentrations” (and therefore biologic activity) “are dependent on the concentration of free rather than protein-bound hormone in the plasma” (Mendel, 1989). The level of free testosterone correlates to clinical symptoms of hypogonadism more closely than the level of total testosterone.

Testosterone and DHT are converted to inactive metabolites primarily by the liver. In the liver, oxidoreductases such as 3 α - and 3 β -hydroxysteroid dehydrogenases perform oxidoreduction, and the metabolites are then conjugated by glucuronidases. The inactivated metabolites are excreted into urine and bile (Gao et al., 2005).

Testosterone and Its Receptors

Humans have estrogen, progesterone, androgen, glucocorticoid, and mineralocorticoid receptors. These receptors have a hinge region, a hormone-binding domain, a DNA-binding domain, and a variable domain. The nuclear localization signal, which helps the receptor enter the nucleus, is located by the hinge region and is blocked by heat shock proteins (Gao et al., 2005). There are several isoforms of androgen receptors. Androgen receptors are primarily found in the cytoplasm. Free testosterone diffuses into the cell. If 5-alpha-reductase is present, the testosterone is converted into dihydrotestosterone. In the cytoplasm, the androgen is bound by the androgen receptor. The heat shock proteins dissociate from the androgen receptor, and the receptor is dimerized, phosphorylated, and translocated to the nucleus. In the nucleus, the androgen receptor dimer acts as a transcription factor to regulate gene expression via binding to the hormone response element (Gao et al., 2005). The androgen receptor also interacts with other transcription coregulators.

There are also nongenomic, rapid effects of androgens that is mediated via membrane androgen receptors. Even if the androgen is prevented from entering the cell, it can still cause changes in intracellular calcium, via membrane androgen receptors such as

Fig. 3 Testicular steroidogenesis.

GPRC6A and ZIP9. These membrane androgen receptors affect ion transport channels via signal transduction proteins such as PI3k/Akt, Src, and Protein Kinase C (Hatzoglou et al., 2005).

Polymorphisms in the androgen receptor can alter the transcriptional activity of the androgen receptor. Androgen receptor genes with longer CAG repeat sequences are correlated with lower transcriptional activity. Certain polymorphisms have been linked to osteoporosis, infertility, prostate cancer, and androgenic alopecia. Because of diminished androgen feedback, patients with longer CAG repeats may have higher serum testosterone concentrations (Zitzmann and Nieschlag, 2003).

Effects of Testosterone

Human male and female gonads are the same until 6–7 weeks of fetal age. During the 7th week, differentiation begins. The precursors of the Leydig cells produce androgens as early as 6–7 weeks of gestation, preceding the secretion of LH by the pituitary. The Leydig cells reach their peak development and maturation around 17–21 weeks of gestation (Svechnikov et al., 2010). Testosterone is responsible for the development of the Wolffian duct and the structures such as the epididymis, prostate, seminal vesicles. The development of the external genitalia (including formation of the glans penis and corpora cavernosa), scrotal thinning and formation of rugae is dependent upon the presence of DHT.

During puberty, testosterone is required for development of secondary sexual characteristics (virilization) and spermatogenesis. Testosterone leads to growth of the penis, scrotum, prostate, and seminal vesicles. It also leads to the development of male pattern hair, increased sebum production (which may lead to acne), and deepening of the voice. It stimulates IGF-1 and growth hormone secretion. Testosterone and estradiol are involved in skeletal growth and increase in bone mineral density. Testosterone is also

involved in stimulation of libido, increase in skeletal muscle mass, redistribution and decrease of body fat, and decrease in HDL. During adulthood, testosterone maintains adult male characteristics, sexual function, and spermatogenesis. It is also involved in the stimulation of erythropoiesis.

As mentioned above, dihydrotestosterone is required in the formation of the male external genitalia. It also leads to facial and body hair, acne, male pattern baldness, and prostate growth. It is the primary androgen in the prostate, seminal vesicles, skin, and hair follicles in adults. In the setting of congenital 5-alpha-reductase 2 deficiency, the male genitalia and prostate are underdeveloped, but during puberty the testosterone levels rise normally and they develop male musculature. Persons with 5-alpha-reductase deficiency have lower levels of pubic and body hair, and do not develop androgenic alopecia.

With aging, testosterone levels tend to fall, thus there tends to be a loss of lean muscle mass and an increase in fat mass. It is controversial whether this decline is pathologic and whether it benefits from treatment, although the positive effects of testosterone on libido, muscle mass, and bone mineral density have been shown (Snyder et al., 2016; Wu et al., 2010).

Hypogonadism and Its Effects

Hypogonadism has various effects depending on the stage of development of the patient. In fetal development, androgen insensitivity syndrome or congenital defects in testosterone synthesis leads to ambiguous genitalia. In prepubertal children, androgen deficiency causes eunuchoidism, signs of which include small testes (<4 mL), infantile genitalia, high-pitched voice, and disproportionately long arms and legs relative to height, which may manifest as arm span greater than height or increased lower-to-upper body ratio. Adults who develop hypogonadism may have changes in their mental status, including lower motivation, decreased energy, depressed mood or irritability, and decreased concentration or memory. There is a decrease in libido/sexual function and fertility. They may have hyperlipidemia and insulin resistance. On examination of their semen, they may have sperm with abnormal morphologies (teratozoospermia), sperm with reduced motility (asthenozoospermia), low sperm count (oligozoospermia), or no sperm cells in the ejaculate (azoospermia). With longstanding androgen deficiency, there may be loss of androgen-dependent hair, reduced muscle mass, development of fine facial wrinkles, gynecomastia, reduction in prostate size, decreased bone mineral density, and decrease in testes volume. If the development of testosterone deficiency is rapid, they may have hot flashes and sweats.

Hypogonadism can be primary (primary testicular failure) or secondary (central hypogonadism or hypogonadotrophic hypogonadism) (Fig. 1). Primary testicular failure can be differentiated from hypogonadotrophic hypogonadism by measurement of FSH, LH, and testosterone levels. In both primary and secondary hypogonadism, testosterone levels are low. However, in primary hypogonadism, FSH and LH levels are elevated, whereas in secondary hypogonadism, FSH and LH are low. Causes of primary testicular failure include Klinefelter syndrome, testicular injury, and chemotherapeutic agents and irradiation. Causes of hypogonadotrophic hypogonadism include pituitary tumors, hemochromatosis, injury to the pituitary, Kallmann's syndrome, acute and chronic illnesses, medications including opioids, and obesity.

Conclusion

The hypothalamic-pituitary-testis axis controls testosterone production, and can be affected by internal and external factors. Recent studies have elucidated more details on the KNDy neurons and kisspeptin in the control of GnRH secretion and the mechanism of GnRH pulse generation. Pulsatile GnRH secretion results in the production and secretion of LH and FSH by the pituitary regulating testicular function. The testes are responsible for spermatogenesis and the production of androgens mainly, testosterone. Testosterone and its metabolites estradiol and DHT have paracrine and systemic effects, and defects in testosterone biosynthesis or testosterone receptor function can lead to hypogonadism.

TESTIS CELL BIOLOGY

Sertoli Cell

Bernard Jégou and Antoine D Rolland, Univ Rennes, Inserm, EHESP, Irset (Institut de recherche en santé, environnement et travail) - UMR_S 1085, Rennes, France

Introduction

In 1865 at the age of 23 years, the Italian scientist Enrico Sertoli described for the first time the “cellule ramificata” (Sertoli, 1865; Setchell, 1993) within the human testis. His Austrian contemporary Victor von Ebner 13 years after the description called the cell a Sertoli cell, which has now been accepted for more than a century as the Sertoli cell (von Ebner, 1888). From the start Sertoli had made the assertions that the Sertoli cells which cover the wall of the seminiferous tubules in mammals were (i) individual cells; and (ii) linked to the production of spermatozoa within the seminiferous tubules. Then for decades, the Sertoli cells fascinated the histologists, but it is only with the advent of the electron microscope in the second half of the 20th century that Fawcett and Burgos (1956) ended the controversy about the possible syncytial status of the Sertoli cells by establishing that there are indeed individual cells.

Description of the Sertoli Cell

The Sertoli cell presents complex shapes (the “cellule ramificata”) which vary according to the different stages of spermatogenesis and extends from the basal lamina of the seminiferous tubules toward the lumen of these tubules (Fig. 1). This organization and polarity of the Sertoli cells is reflected by junctions between neighboring Sertoli cells and germ cells at different stages of differentiation, as well at the level of the wall the seminiferous tubules between the Sertoli cells and the extracellular matrix. The discovery and description of the cellular structural devices within the seminiferous tubules was essential in deciphering the extremely complex Sertoli cell–germ cell communication network (Fig. 1).

The structure and function of the structural devices from Sertoli cells and other tubular cells have been extensively reviewed (Russell, 1993; Jégou, 1991, 1992, 1993; Mruk and Cheng, 2015). We can classify them into three categories: (i) devices that are implicated in cell attachment, shape, and movement. These include the desmosome-like and ectoplasmic specializations; (ii) devices which combine their involvement in the functions described just before (i), but also which are involved in the transfer of cellular materials and molecules from Sertoli cells to germ cells or vice-versa: the spermatogonial processes, the tubulobulbar complexes, the spermatid processes and gap junctions; (iii) devices only involved in the transfer of materials such as the residual bodies which are formed from the elongated spermatids and detach in the lumen of the tubules when spermatozoa are released. Residual bodies are phagocytosed by the Sertoli cells.

Fig. 1 Schematic representation of the intratesticular organization. Adapted from Rolland, A. D., Jégou, B. and Pineau, C. (2008). Testicular development and spermatogenesis: Harvesting the postgenomics bounty. *Advances in Experimental Medicine and Biology* **636**, 16–41. doi: 10.1007/978-0-387-09597-4_2.

Over the last decades, progress in deciphering the molecular bases of structural devices and the spatio-temporal regulation of molecules interconnecting the Sertoli cells and the germ cells has been instrumental to understand better how the testis functions and assumes its role in producing spermatozoa and various hormones important for spermatogenesis, and in men's health more generally.

How Do Sertoli Cells Control Spermatogenesis?

The Sertoli Cell Barrier

This structure was defined by as lying within the specialized Sertoli cell junctional complexes located in the basal segment of the seminiferous epithelium (Ploën and Setchell, 1992). This barrier is selective and divides the seminiferous epithelium into a basal compartment, that comprises the premeiotic germ cell categories, and an adluminal compartment, that encompasses meiotic and post-meiotic germ cells, the latter being the haploid spermatids at all steps of their development. Of note is that the Sertoli cell barrier is a crucial component of the so-called blood–testis barrier, which also comprises the blood vessels and the peritubular cells.

The Sertoli cell barrier is essential to (i) assume the cytoarchitecture of the Sertoli cell; (ii) produce the tubular fluid and create and maintain the micro-environment which is essential to meiosis and spermiogenesis (i.e., differentiation of the spermatids); (iii) establish distinct domains of the Sertoli cell plasma membrane such as the presentation of the FSH membrane receptors at the basal pole of the cell (Fawcett and Burgos, 1956); implement the immunological barrier which prevent antigens from the meiotic and post-meiotic germ cells to generate immune reactions which would be deleterious to fertility. According to several authors, FSH and testosterone are most likely involved in the formation, control, and maintenance of the Sertoli cell barrier (de Kretser and Burger, 1972; Kerr et al., 1993).

The Products of the Sertoli Cells Destinated to Germ Cells

It is now well established that the Sertoli cell produce the tubular fluid, peptides, proteins, and steroids (Bardin et al., 1988; Griswold, 1988; Jégou, 1992, 1993). This justifies its ancestral name of “nurse cell,” that is the cell which provides a crucial assistance for spermatogenesis to occur. While the products of the Sertoli cells were historically thought to be addressed toward the lumen of the tubules where the fluid transports freshly shed and nonmotile spermatozoa, it is now known that the Sertoli cell products necessary to early germ cells, peritubular myoid cells, and Leydig cells are secreted and directed basally, while those required for meiosis and spermiogenesis are likely to be directed apically (Gunsalus and Bardin, 1991; Byers et al., 1993).

The Hormonal Activity of the Sertoli Cells

Among the proteins produced by the Sertoli cells are the hormones named inhibin and activin which play a key role in the negative and positive retrocontrols on the production of FSH, respectively. Another key protein hormone which is exclusively produced by the Sertoli cell is the anti-Müllerian Hormone (AMH). AMH induces the resorption of the Müllerian ducts to favor the masculinization of the urogenital tract during fetal life. Of note is that AMH is still produced at all ages of life, but its paracrine role (i.e., within the seminiferous tubule) as well as its endocrine function (through the blood circulation) are largely unknown in the adult male. Last but not least, whether the estrogens produced by the immature Sertoli cells exert a hormonal control (i.e., outside the seminiferous tubules) remains to be established.

How Do Germ Cells Control Sertoli Cell Function?

Evidence for a Germ Cell Control

The qualification of the Sertoli cell as a “nurse cell” has occulted for a long time the fact that germ cells which represent about 70%–80% of the volume of the seminiferous tubule exert an essential feedback on it. Thus, the incredible plasticity of the seminiferous epithelium all along spermatogenesis exerts enormous cyclic constraints on the Sertoli cell cytoskeleton, illustrating the axiom that “structure is the function.” Sertoli cell function is for a large part dictated by the changing number, nature, and needs of the germ cell complements (Jégou, 1991, 1992, 1993). This has been experimentally established using (i) in vivo approaches by the implementation of various exposures (radiation, moderate heat, chemical agents) able to induce selective loss of a (or a limited) germ cell category (ies), and thereby inducing changes in the morphology and function of the Sertoli cell which can be observed and measured; (ii) in vitro, thanks to the culture and co-culture of isolated Sertoli cells and various categories of germ cells (Jégou, 1992, 1993). The microdissection of rat seminiferous tubules at the different stages of spermatogenesis owing to the transillumination of the tubules has also allowed demonstrating the spatio-temporal expression and production of a number of Sertoli cell products (Parvinen, 1993).

Mechanisms of the Germ Cell Control

We have hypothesized that there are different pathways by which germ cells exert their action on the Sertoli cells. These pathways represent a combination of (i) morphoregulatory mechanisms and membrane molecules (Gérard et al., 1995; Byers et al., 1993; Mruk and Cheng, 2015); (ii) the transfer of enormous amounts of germ cell materials all along the spermatogenetic process (Jégou and Sharpe, 1993); and (iii) soluble proteins from germ cell even though the extreme fragility and lability of isolated germ cells have hampered their intensive identification and study (Jégou, 1991, 1992, 1993).

The Sertoli Cell–Peritubular Cell Cross Talk

A lot of mystery remains on how the cells that border the tubules—the peritubular myoid cells—and the Sertoli cells actually dialogue. It remains that this dialogue is no doubt important from fetal life to adulthood to ensure the polarity and full functionality of Sertoli cells (Skinner, 1991; Jégou and Sharpe, 1993). This involves the co-production of extracellular matrix of the laminae propria, the production of molecules, the receptivity vis-à-vis different hormones (testosterone, FSH) and metabolic cooperations.

Fig. 2 Drawing from a three-dimensional reconstructed stage V rat Sertoli cell. From Wong, V. and Russell, L. D. (1983). Three-dimensional reconstruction of a rat stage V Sertoli cell: I. Methods, basic configuration, and dimensions. *The American Journal of Anatomy* **167**, 143–161.

The Sertoli Cell–Leydig Cell Cross Talk

The fact that the testis is divided in two compartments, the seminiferous tubules where Sertoli cells reside and the interstitial tissue where the Leydig cells are situated is not antinomic to the existence of a finely tuned and essential dialogue between Sertoli cells and Leydig cells for testicular function and men's health to be optimum. The dialogue between these two somatic cell types involve the interstitial fluid and the steroids (oestradiol and testosterone) as well as peptides and protein factors, the latter being far from having all been identified. It also involves the extracellular matrix and aspects of the mediation assumed by the peritubular cells which also remain largely unexplored.

Conclusion

The late Lonnie Russell who has remarkably studied and reviewed the “form, dimensions, and cytology of mammalian Sertoli cells” used to insist on their extraordinary well developed cytoskeleton, involving the classical actin and intermediate filaments as well as microtubules (Russell, 1993) (Fig. 2). This cytoskeleton displays all possible properties of plasticity to adapt to the cyclicity of spermatogenesis and its regulation. No doubt that the development of new imaging technologies, and the input of all aspects of other technologies which have irrigated the field of biology and medicine over the last decades will allow to fill the numerous gaps which still represent an obstacle to understand better the intimacy of the Sertoli cell and thereby of the physiology of the testis.

Over 150 years ago Enrico Sertoli first suggested that the cell which now bears his name was a “sustentacular” or nurse cell. This suggestion was made because of the observed morphological relationships with the developing germ cells. The morphology of Sertoli cells has been described in some detail but even after years of research with new and better technological tools many of the complex functions of the Sertoli cells remain obscure. It has been shown that it is the expression of genes in embryonic Sertoli cells encoding transcription factors such as Sry and Sox9 that result in the formation of the testis (for a review see [Svingen and Koopman, 2013](#)). Gene expression in Sertoli cells is very dynamic beginning early in embryogenesis, has a role during the onset of spermatogenesis and throughout the reproductive lifetime of the organism.

The initial molecular studies on Sertoli cells began in the 1970s and 1980s when the techniques for primary culture were described ([Dorrington et al., 1975](#); [Steinberger et al., 1975](#)). The availability of enriched primary cultures of Sertoli cells and specific antibodies combined with improvements in microscopy have revealed several gene products that are required for the function of Sertoli cells. In the early 1980s it was shown the Sertoli cells secreted metal transport proteins such as transferrin and ceruloplasmin ([Skinner and Griswold, 1980](#)). It was initially proposed that the transport of metals by Sertoli cell gene products to developing germ cells was an example of the “nurse cell function.” This idea has been modified as the components of the iron transport pathway in the testis were described ([Leichtmann-Bardoo et al., 2012](#)). It was proposed that there was an iron cycle in the testis that was orchestrated by the Sertoli cells. It was proposed that iron was delivered by the Sertoli cells to the developing germ cells to support mitosis, meiosis, and mitochondriogenesis through the elongated spermatid stage. The bulk of the iron was then recycled back to the Sertoli cells in the ingested residual bodies where it could again be delivered to another stage of developing germ cells. In this proposed model, the nurse cell function of the Sertoli cells involved the provision and delivery of iron but also the removal and recycling of the potential toxic accumulation of iron in the residual bodies. It is likely that there are several such mechanisms that involve delivery and recycling of critical components for germ cell development.

Sertoli cells products can inhibit immune reactions and provide structural features under a broad classification of “bioprotective and structural” functions ([Franca et al., 2016](#)). Adjacent Sertoli cells synthesize the components of the tight junction complexes and contribute to the basement membrane and participate in the formation of desmosomes, gap junctions and some unique forms of junctions with germ cells. The nature of spermatogenesis results in the production of enormous numbers of gametes and therefore these structural elements must be extremely dynamic and involve the spatiotemporal expression of many genes.

A key molecular event in the Sertoli cells is the response to FSH and testosterone and the subsequent production of paracrine factors that regulate germ cell development ([Griswold et al., 1988](#)). Both FSH and testosterone act through Sertoli cells to alter gene expression throughout development and with the stage of the cycle of the seminiferous epithelium. Another key signaling molecule in spermatogenesis is vitamin A in the form of retinoic acid. The onset of germ cells committing to meiosis requires retinoic acid and the source of retinoic acid to initiate spermatogenesis are the Sertoli cells ([Hogarth and Griswold, 2010](#)).

The in vitro differentiation of germ cells into functional gametes has been reported for several species. These reports would suggest that the progression of stem germ cells into functional gametes is an autonomous program. However, even optimistically accepting the results from the most successful of these reports it is clear that germ cells in the absence of Sertoli cells are extremely inefficient at sperm production when compared to spermatogenesis in the testis. Clearly gene products from Sertoli cells are required for the efficient formation of functional gametes. Gene products from Sertoli cells provide the environment, the signaling, the immunoprotection and the structural components to promote the efficient differentiation of male germ cells into spermatozoa. While germ cells must have an autonomous program, Sertoli cells appear to be “permissive” in nature ([Russell and Griswold, 1993](#)).

One of the major issues surrounding studies on the molecular biology of Sertoli cells is the complexity of the testis histology and the close association of many different cell types. The ability to culture relatively pure Sertoli cell preparations allowed for some molecular studies but the removal of Sertoli cells from the testis and the in vitro culture can alter the results. A recent innovation is the use of the RiboTag mouse that allows the genetic tagging of polysomes in Sertoli cells in vivo. This technology has resulted in the ability to analyze mRNA associated with polysomes in vivo in a single cell type amongst many cell types in a complex tissue ([Sanz et al., 2013](#)). The use of the RiboTag mouse has revealed some genes that are overexpressed in Sertoli cells relative to the other cell types in the testis and provide clues as to specific functions within the cell. Genes involved in glutathione metabolism, cytochrome P450 enzymes, drug metabolism pathways, peptidase and enzyme inhibitor pathways were relatively overexpressed by adult Sertoli cells in vivo ([De Gendt et al., 2014](#)). These results emphasize the importance of the detoxifying role of Sertoli cells.

When examined in the context of testis biology, the molecular details of the function of Sertoli cells must be well controlled. It appears that Sertoli cells participate in multiple aspects of spermatogenesis with gene expression varying with stages of the cycle of the seminiferous epithelium and as a result of different endocrine signals. In addition, this variable gene expression must be present throughout the reproductive lifetime of the organism.

Introduction

Leydig cells (LC) belong to the somatic cell complement of the testis and are located in the interstitial tissue, that is, the space between seminiferous tubules (**Fig. 1**). Their role is to produce sex steroids, in particular testosterone (T) for the paracrine regulation of spermatogenesis within the testis, and for the various systemic endocrine effects, androgenic and anabolic, outside the testis. Next to T, LC produce another hormone, insulin-like 3 (INSL3), that plays a pivotal role in fetal life in the regulation of testicular descent. Testicular endocrine activity starts in utero, when T produced by fetal LC (FLC), and its metabolite 5 α -dihydrotestosterone (5 α -DHT), induce masculinization of the male genital structures. LC activity declines after birth and becomes reactivated just before puberty when most FLC have disappeared and replaced by adult LC (ALC). These ALC continue to produce T, though a slight decline in their endocrine activity occurs with aging (**Huhtaniemi, 2014**). The purpose of this chapter is to present an updated summary of salient features of the differentiation, regulation and function of LC, as well as their clinical aspects, along a male's lifespan. The main emphasis will be on two model species, i.e. the human and rodent (rats and mice).

Leydig Cell Development

Fetal Development

Following activation of the SRY gene located on the Y chromosome, the undifferentiated gonad differentiates into a testis. Within the testis two distinct compartments can be identified, that is, the testicular cords and the interstitium. Rodent studies have shown that the cells populating the interstitium form a diverse pool. Among these cells are Wilm's tumor 1 (WT1)+/Hairy and enhancer of

Fig. 1 (A) Light-microscopic picture of rat testis, showing the location of LC (arrows) in the interstitial tissue; (B) electron-microscopic (EM) picture of a mouse LC showing the main organelles (lipid droplets, mitochondria, and SEM); (C) EM picture of a monkey LC showing Reinke crystals. split 1 (HES1)- and WT1 +/HES1 + cells, which are considered to be the progenitors from which the FLC population develops, implicating that the FLC population originates from two different lineages (Liu et al., 2016). During embryonic development a dramatic increase in the number of FLC occurs to provide sufficient amounts of androgens to virilize the male embryo. The increase in the size of the FLC population takes place mainly through recruitment from the progenitor pool, as differentiated FLC are mitotically inactive (reviewed in Teerds and Huhtaniemi, 2015).

Neonatal Development

The fate of the FLC after birth is dependent on the species. In rodents the FLC population regresses after birth and concomitant androgen production decreases until the development of the new population of ALC is initiated.

In humans on the other hand, most FLC already undergo involution during the second half of fetal life, when placental hCG production decreases. Some FLC escape involution and continue to be steroidogenically active throughout pregnancy. In the first few months after birth, neonatal activation of the hypothalamic-pituitary-testicular (HPT) axis occurs ("minipuberty"), through the elimination of negative feedback of placental steroids, leading to the establishment of a neonatal population of LC, originating from the surviving FLC as well as through differentiation of stem LC (SLC). This process is unique to primates and leads to the development of a highly active neonatal LC population, which may promote the imprinting of various cell types in androgen dependent organs, including the brain (reviewed in Teerds and Huhtaniemi, 2015). The neonatal activation of the HPT axis is only temporary and followed after about 6 months of life by a prolonged period of inactivity of pituitary gonadotropin secretion and concomitant steroidogenic quiescence until just before puberty.

Pubertal-Adult Development

Although there has been no doubt that, like the FLC population, ALC arise from stem cells that have their origin in the fetal testis, it was not until recently through lineage-tracing that the origin of this stem cell was brought to light. Rodent studies have revealed that part of the interstitial WT1 +/HES1 + progenitor cells lose WT1 expression between E10.5 and E12.5 but retain HES1, and acquire the expression of Glioma associated gene 1 (GLI1), a transcription factor involved in the hedgehog (Hh) signaling pathway. These WT1 –/HES1 +/GLI1 + expressing cells do not acquire CYP17A1 expression and thus steroidogenic capacity. They are thought to give rise to the ALC population that develops around puberty. Lineage-tracing studies further reveal that activation of the desert hedgehog (Dhh) signal transduction pathway plays an essential role in FLC and ALC development, but also reveal that FLC and ALC arise from different stem cells (Liu et al., 2016).

After birth in the neonatal rodent testis expression of lineage specific markers such as luteinizing hormone receptor (Lhr) and steroidogenic enzymes remains absent in SLC. Like FLC, postnatal SLC are characterized by the expression of platelet-derived growth factor receptor α (Pdgfra), GATA binding protein 4 (Gata4) and stem cell markers such as c-Kit and leukemia-inhibiting factor receptor (Lifr). In vitro experiments have disclosed that factors like LIF, stem cell factor (Scf), epithelial growth factor (Egf), fibroblast-like growth factor 2 (Fgf2), and platelet-derived growth factor α (Pdgfa) are important regulators of SLC proliferation. Differentiation of these cells into steroid producing progenitor LC (PLC), the second stage of ALC development, is induced by culturing SLC among others in the presence of LH, insulin-like growth factor 1 (Igf1), and thyroid hormone (reviewed in Teerds and Huhtaniemi, 2015).

Further proliferation and maturation of PLC into immature LC (ILC) and mature ALC is highly dependent on the presence of thyroid hormone and LH and will be discussed in more detail later.

Old Age

Deciphering the effect of aging on LC function is complicated by the concomitant acquisition in many men of obesity and chronic diseases, whose effects on HPT function differ from those of aging. The isolated aging effect in human males includes a decrease in the average total number of Leydig cells per testis by 44% between 20–48 and 50–76 years of age (Neaves et al., 1984). The reduced LC mass is able to maintain T production within the normal range of eugonadism in most aging men. In some men it initially leads to compensated primary hypogonadism (normal T, high LH) and subsequently to primary hypogonadism (low T, high LH) (Huhtaniemi, 2014). In rodents, the age-related reduction in T is predominantly due to unresponsiveness of the LC to LH (Wang et al., 2017). The decrease in T is more pronounced if the aging man is obese or has chronic diseases, in which case the gonadotropin compensation does not occur.

Leydig Cell Morphology

Fetal Leydig Cells

Mature FLC are characterized by a round nucleus, an abundant network of smooth endoplasmic reticulum (SER), mitochondria with tubulovesicular cristae, a small to moderately sized Golgi apparatus, numerous large lipid droplets and finger-like cell surface protrusions; the cells are often arranged in clusters in the interstitium.

In contrast to rodents where FLC undergo regression after birth, in the human testis the majority of FLC undergoes regression during the second trimester of pregnancy. The involution of the FLC population is associated with a decrease in cell volume, and the appearance of electron-dense cells (Haider, 2004).

Adult Leydig Cells

The morphological differences between FLC and ALC are relatively small (Fig. 1B). In rodents the most striking difference between these two types of LC is less abundant lipid droplets in the cytoplasm of mature ALC (Haider, 2004). This is in contrast to the human and primate testis where lipid droplets continue to be part of the cytoplasm of mature ALC. Another typical morphological characteristic of primate ALC is the presence of Reinke crystals in the cytoplasm (Fig. 1C). Although this structure has been studied extensively, no function has been attributed to it. Reinke crystals are not unique to the human testis but have been identified in Leydig cells of a few other species including the guinea pig (Prince, 2007).

Aged Leydig Cells

Ultrastructural analysis of the aging testis has revealed that many LC preserve their normal morphological appearance. Other LC acquire increased numbers of cytoplasmic or intranuclear Reinke crystals or paracrystalline inclusions (primate Leydig cells), multiple vacuoles, lipofuscin granules and lipid-laden cytoplasm, and show signs of dedifferentiation and involution with poorly developed endoplasmic reticulum and mitochondria, as well as presence of two or three nuclei (reviewed by Perheentupa and Huhtaniemi, 2009). These morphological alterations support the observations of decreased LC functionality in the aged testis. There is apparent correlation between the amount of deformed LC and the decrease in T production. Decreased testicular perfusion caused by atherosclerotic alterations in testicular arterioles may be the primary reason for the observed degenerative changes in LC and their reduced steroidogenic capacity during aging.

Leydig Cell Functions

Steroid Hormone Production

The most important steroid hormones produced by LC are androgens, in particular T. Steroidogenesis occurs under tropic regulation of the pituitary gonadotropin LH, and its action is modulated by numerous other endocrine, paracrine and autocrine factors (see below). Most details of the synthesis, secretion and metabolism of testicular steroid hormones have been unraveled in the 1950s and 1960s. Newer information about androgens concerns the identification and characterization of the steroidogenic enzyme genes and proteins, the mechanisms of cholesterol supply for steroid biosynthesis (see below), as well as the mechanisms of androgen action.

Androgens are essential for all masculine functions of the body, including sexual differentiation, development of secondary sex characteristics, spermatogenesis, masculine features of the muscle–bone apparatus, and male sexual behavior.

Canonical pathway of steroidogenesis

The synthesis of steroid hormones starts from cholesterol, for which LC have multiple sources: (a) de novo synthesis from acetyl coenzyme A, (b) stored cholesteryl esters, (c) exogenous lipoprotein-supplied cholesterol, and (d) plasma membrane-derived cholesterol (Tremblay, 2015). The most utilized source is the plasma low- and/or high-density lipoprotein–cholesterol complexes, endocytosed by receptor-mediated mechanisms. Cholesterol is thereafter esterified and stored in intracellular lipid droplets.

The next step is the trans-cytoplasmic transport of cholesterol from lipid droplets to the outer mitochondrial membrane by yet poorly understood mechanisms. The subsequent transfer of cholesterol from the outer to the inner mitochondrial membrane has been better characterized. This rapid step (within minutes) is rate-limiting and critically dependent on LH stimulation. A crucial role here is played by functional interaction of at least two proteins, that is, the steroidogenic acute regulatory protein (StAR) and the 18 kDa translocator protein (TSPO) (Rone et al., 2009). Inactivating mutations of the *StAR* gene lead to congenital lipoid adrenal hyperplasia, which condition is in principle lethal and characterized by a near complete blockade of steroidogenesis in adrenal cortex and gonads.

The next step in steroid biosynthesis, at the mitochondrial inner membrane, is the conversion of cholesterol to pregnenolone, catalyzed by the cytochrome P450 cholesterol side chain cleavage enzyme (P450_{sc}, CYP11A1) and auxiliary electron transferring proteins (Fig. 2). For the following steps, pregnenolone has to translocate from the mitochondria to the SER. Depending on the order of enzymatic reactions, two alternative pathways, Δ^5 or Δ^4 , are employed (Fig. 2). The preferred pathway depends on age and species, but the Δ^5 pathway is predominant in humans and the Δ^4 pathway in rodents. In the former, pregnenolone is first converted by the same cytochrome P450c17 (CYP17A1) enzyme via 17-hydroxypregnenolone (17-hydroxylation step) to dehydroepiandrosterone (lyase step). The following steps, in alternate order, are either the conversion of the 3 β -hydroxy-5-ene structure of dehydroepiandrosterone by 3 β -hydroxysteroid dehydrogenase/isomerase (HSD3B2) to the 3-keto-4-ene structure of androstenedione, or the reduction of dehydroepiandrosterone by 17 β -hydroxysteroid dehydrogenase (HSD17B3) to 5-androstene-3 β ,17 β -diol, with final formation of T after the two reactions taking place in alternate order. In the Δ^4 pathway, the first metabolic step after pregnenolone is its HSD3B2-catalyzed conversion to progesterone, after which the metabolism

Fig. 2 The “classical” and alternative/backdoor pathways of androgen synthesis in LC. The factors functional in the classic pathway are CYP11A1 (cholesterol side-chain cleavage enzyme, P450_{scc}), CYP17A1 (17 α -hydroxylase/17,20-lyase, P450_{c17}), HSD3B2 (3 β -hydroxysteroid dehydrogenase, type 2), HSD17B3 (17 β -HSD3 [17 β -hydroxysteroid dehydrogenase, type 3]) and 5 α -reductase, type 2 (5 α -reductase 2, encoded by SRD5A2). The alternative/backdoor pathway uses the following additional enzymes: 5 α -reductase, type 1 (5 α -reductase 1, encoded by SRD5A1), AKR1C2 3 (3 α -reductase, type 3) and possibly AKR1C4 (3 α -reductase, type1) and RoDH (3-hydroxyepimerase, encoded by HSD17B6). The trivial names and abbreviations of the steroids are: 17-hydroxydihydroprogesterone (17OH-DHP), 5 α -pregnane-17 α -hydroxy-3,20-dione; 17-hydroxy-allopregnanolone (17OH-allo), 5 α -pregnane-3 α ,17 α -dihydroxy-20-one; 5 α -dihydroprogesterone (5 α -DHP), 5 α -pregnane-3,20-dione; allopregnanolone, 3 α -hydroxy-5 α -pregnan-20-one.

proceeds further through 3-keto-4-ene intermediates to T (Fig. 2). Except for the 17 β -HSD step all conversions are irreversible. An interesting detail about FLC is that their androgen production stops at androstenedione, and the last conversion of its 17-keto to 17 β -hydroxy group of T, catalyzed by HSD17B3 (Fig. 2), occurs in Sertoli cells in the seminiferous tubules (Fig. 1).

The daily production of T in a male is 6–7 mg, of which about 95% originates from the testes and the rest through peripheral conversion of testicular and adrenal androgenic precursors into T. LC produce also other steroid hormones, most of these are Δ^4 and Δ^5 intermediates of T synthesis. Some have weak androgenic activity (e.g., androsterone) or will be metabolized further in the testis or peripheral tissues. High concentrations of human testicular steroids are stored and secreted as functionally inert sulfate conjugates. The testis also produces small amounts of 5 α -DHT, which is the active molecular form in many extra-testicular actions of androgens (e.g., hair follicle and prostate). Likewise, a small number of androgens are aromatized to estrogens through action of CYP19 (P450_{arom}) within the testis tissue or in periphery (adipose and brain tissue).

Alternative pathway of androgen synthesis

While T is the main androgen produced by FLC, its conversion to the more bioactive androgen 5 α -DHT is important for masculinization of the external male genitalia. 5 α -DHT was formerly considered to be solely metabolized from T by the action of 5 α -reductase type 2 (SRD5A2) in genital skin, because males with inactivation of this gene have ambiguous genitalia, that is, disorder of sexual differentiation (DSD). Surprisingly, recent studies on specific cases of DSD have revealed that a significant proportion of fetal 5 α -DHT is produced from progesterone using the alternative or “backdoor” metabolic pathway with 5 α -dihydroprogesterone, allopregnanolone, 17-hydroxyallopregnanolone, androsterone, and androstanediol as intermediates (Fig. 2) (Flück and Pandey, 2014). The key enzymes in this pathway, not employed by the classical steroidogenic pathway, are the α -keto-reductases AKR2 and AKR4, of which the former converts androstanediol to 5 α -DHT. Because human males with SRD5A2 and AKR2/4 deficiency present with ambiguous genitalia, also the backdoor pathway is needed for normal male fetal masculinization.

INSL3

A nonsteroidal hormone produced by LC is insulin-like 3 (INSL3), which is a member of the insulin-relaxin family of peptides, acting through a G-protein coupled receptor relaxin/insulin-like family peptide receptor 2 (RXFP2) (Ivell et al., 2017). Its production starts in rodent and human FLC around the same stage of fetal development and is largely autonomous. It is expressed in both mature FLC and ALC, and its only clearly established function so far is its role, along with androgens, in the trans-abdominal testicular descent in fetal life. Evidence for this role of Insl3 and its receptor Rxfp2 comes from knockout mice, which present with a high degree of intraabdominal cryptorchidism.

There are also data on the role of INSL3 in the modulation of bone metabolism, as a regulator of steroid production and as sperm cell survival factor within the testis. Its concentration in serum correlates best with the number of functional LC in the testes (Ivell et al., 2017).

Intratesticular Hormone Levels

The intratesticular concentration of T in the human is about $2.5 \mu\text{mol L}^{-1}$ and although somewhat less in rodents, it is still in general 50–100-fold higher than in the peripheral circulation (Table 1). This high intratesticular concentration of T is considered critical for the maintenance of spermatogenesis. A drastic reduction in intratesticular T concentrations during treatment with gonadotropin-releasing hormone (GnRH) analogues or T, suppressing LH and FSH secretion, causes a blockage of spermatogenesis. Therefore, T treatment seems a promising hormonal male contraceptive (see below).

It remains an enigma why the intratesticular T concentration is so high to maintain spermatogenesis, as it by far exceeds the concentration needed to activate androgen receptors. A banal explanation, supported by recent experimental data, is that the concentration is so high only because the testis is the site of T synthesis (Oduwole et al., 2014); a much lower threshold concentration may be sufficient for spermatogenesis to proceed.

Leydig Cell Hormone Secretion

The secretion of steroid hormones from LC is considered a passive process due to their lipid solubility and ease of transit through cell membranes. The main steroid hormones produced and secreted by the human testis are listed in Table 1. T and the sulfate conjugates of pregnenolone, dehydroepiandrosterone and 5-androstene- 3β , 17β -diol are quantitatively most abundant. There is no intratesticular storage of bioactive steroid hormones, and the regulation of circulating steroid hormone concentrations occurs mainly at the level of their biosynthesis. Variation in testicular blood flow may be a key factor regulating this process. Since only about $30 \mu\text{g}$ of T is stored in the normal testes (Leinonen et al., 1981), the total T content has to turn over 200 times per day in order to produce the daily 6 mg needed of this hormone. There is diurnal variation in testicular steroid secretion, due to evening/night-time accentuation of LH secretion. Secretion pulses of serum T after the peaks of LH release (average interval of 2 h) are inconsistent, apparently due to the sluggish acute response of human testicular steroidogenesis to gonadotropin stimulation, and to the buffering effect of binding of steroid hormones to plasma transport proteins, in particular sex-hormone-binding globulin (SHBG). Whereas rodent experiments show dramatic (over 10-fold) acute responses of T secretion to LH/human chorionic gonadotropin (hCG) stimulation, the response of human testicular T, within 1–2 h, is only in the order of 30%–50%. A somewhat clearer twofold T response is seen with a 2–4 days' delay.

Regulation of Leydig Cells

Development

Four separate phases have been identified in the formation of the ALC population, based on developmental changes in cell morphology and steroidogenic capacity. The formation of the ALC population is initiated with the differentiation of stem cells. These SLC have an indifferent mesenchymal-like morphology, do not express lineage specific markers such as Lhr and steroidogenic enzymes, and are mainly found in close vicinity of the seminiferous tubules, although there are also reports of a perivascular next to a peritubular localization. The presence of Pdgfra and more recently Cluster of differentiation 90 (CD90) are considered to be important characteristics of SLC and used to isolate and culture these stem cells to study the factors involved in the induction of their differentiation along the LC lineage (reviewed in Teerds and Huhtaniemi, 2015; Li et al., 2017). In vitro studies have revealed that LH, Igf1, Pdgfa, and the active thyroid hormone tri-iodothyronine (T3) contribute to the differentiation of SLC. Recent in vitro evidence shows that next to these factors Dhh is essential for the early commitment of stem cells into the LC lineage, as in the absence of Dhh stem cells fail to differentiate into Lhr positive, steroid producing LC (Li et al., 2017).

Table 1 The mean testicular, spermatic vein and peripheral vein concentrations (in nmol L^{-1}) of the key testicular steroids in man (Leinonen et al., 1981)

Steroid	Testis	Spermatic vein	Peripheral vein
Pregnenolone sulfate	2600	430	90
Progesterone	130	23	0.8
17-Hydroxyprogesterone	690	45	3.2
Dehydroepiandrosterone	680	35	8.2
Dehydroepiandrosterone sunphate	2000	1400	1000
5-Androstene- 3β , 17β -diol	820	590	500
Androstenedione	740	45	2.5
Testosterone	2600	720	20
Testosterone sulfate	1400	150	13
5 α -Dihydrotestosterone	50	14	1.5
Estradiol	15	0.4	0.1

Further support for the role of Igf1 and T3 in SLC differentiation comes from in vivo studies. A targeted deletion of the *Igf1* gene delays the differentiation of SLC into PLC, but does not completely inhibit this process. Daily administration of T3 to newborn rat pups advances the differentiation of SLC into PLC, while a severe reduction in the availability of endogenous T3 leads to a delay in PLC development (reviewed in [Teerds and Huhtaniemi, 2015](#)).

Studies in *Lhr* knockout (LuRKO) mice have shown that beside these factors, LH is of the utmost importance in the differentiation of SLC into PLC. Initially it was reported that inactivation of the *Lhr* completely inhibits the formation of ALC by preventing the differentiation of SLC into PLC. More recently, in vitro studies using SLC isolated from adult rats have shown that in the absence of LH Dhh alone can induce to some extent the formation of T producing PLC ([Li et al., 2017](#)), implicating that limited differentiation of SLC in the absence of LH can occur.

Other factors have been implicated in the process of LC differentiation as well, such as the orphan nuclear receptor chicken-ovalbumin upstream promoter transcription factor II (*Coup-tfII* or NR2F2) and anti-Müllerian hormone (Amh). Time-specific deletion of *Coup-tfII* during late embryonic development does not prevent PLC formation but delays this process, similar to the response to *Amh* overexpression and the previously discussed effects of reduced T3 levels ([Teerds and Huhtaniemi, 2015](#); [Ye et al., 2017](#)).

Depending on the strain of rats, the first PLC develop between day 10 and 13 postpartum, while in primates this process is initiated just before puberty. These cells express *Lhr* and are steroidogenically active, though in contrast to mature ALC, the main androgens produced by PLC are androsterone and androstenedione ([Teerds and Huhtaniemi, 2015](#)).

Pulse chase experiments with [³H]-thymidine have shown that PLC undergo several cycles of proliferation before they differentiate into ILC. Studies on expression levels of marker genes for cell proliferation, for example, proliferating cell nuclear antigen (*Pcna*), *Cyclin a2* and *Cyclin d3* support these observations. Gene cluster analyses further extend these studies, showing high expression of cell cycle regulating genes such as Cell division cycle 25 (*Cdc25*) and *Cdc20* and genes encoding growth factor receptors like *Pdgfra* and *Interleukin-6-receptor* (*Cd126*). The expression of these genes decreases with the transition of PLC into ILC.

With the differentiation of PLC into ILC the cellular characteristics and the position of the cells in the interstitium changes. In the rat model by day 28 postpartum more and more LC translocate to the center of the interstitium. The cytoplasm of the cells contains now a well-developed Golgi apparatus and a large number of tubulovesicular mitochondria and small lipid droplets in which cholesterol is stored to serve as substrate for steroid production. With the transition from PCL to ILC, steroid production switches from androsterone and androstenedione to androstenediol. In contrast to PLC, ILC have only a limited proliferative capacity. Concomitantly, the mRNA and protein levels of *Pcna* and *Cyclins a2* and *d3* decrease while the levels of the cell cycle inhibitor *Cyclin g1* increases ([Teerds and Huhtaniemi, 2015](#); [Ye et al., 2017](#)).

In the rat model by day 50 postpartum ILC have transformed into mature ALC. The latter cells are large and mainly located in the center of the interstitium. The Golgi and mitochondrial complexes have further extended in size and the cytoplasm now contains an abundant SER network. Lipid droplets are no longer part of the cytoplasm, and consequently ALC have switched to another source of cholesterol as steroid precursor, which is now obtained by de novo synthesis or from serum lipoproteins. T has become the major androgen produced by mature ALC ([Teerds and Huhtaniemi, 2015](#)).

Despite the fact that the expression of genes involved in cell proliferation is low in ALC, interstitial cells in the adult testis have not completely lost their potency to proliferate. Pulse-chase experiments and gene cluster analysis have shown that the interstitial cells in the adult testis continue to have a limited capacity to proliferate.

Most studies on the sequence of events that occur along the LC lineage have been performed in rodents. Limited data is available on changes in gene expression and function along the LC lineage in the primate testis (reviewed in [Teerds and Huhtaniemi, 2015](#)).

Endocrine, Para- and Autocrine Regulation

The most important endocrine regulator of LC function is LH, and details of its actions are available in Chapter LH and the male. We describe here the effects of other regulators of LC function.

Several other peripheral hormones have been implicated to participate in the development of the ALC population, some of which have already been discussed, such as the thyroid hormone T3. It is at present not clear whether T3 affects LC development directly or indirectly by binding to thyroid hormone receptor α (Thra) in Sertoli cells.

FSH is another hormone that has been suggested to influence the transition of SLC into PLC, as treatment of prepubertal, hypophysectomized rats with highly purified FSH or recombinant FSH leads to the formation of small numbers of PLC/ILC. These effects of FSH are however indirect as Sertoli cells are the only cell type in the testis to express *Fshr* ([Teerds and Huhtaniemi, 2015](#)).

A considerable number of Sertoli cell-derived factors have been implicated to participate in the development of the ALC population. At present Dhh and *Pdgfra* are considered to be the most important locally produced factors involved. In vivo ablation of Dhh leads to a complicated testicular phenotype. ALC development is negatively affected, but this may in part be due to the fact that Sertoli cell polarity and seminiferous cord formation is severely disturbed ([Clark et al., 2000](#)). In vitro studies suggest that in the absence of LH the effect Dhh on the transition of SLC into PLC is relatively small, while the combined administration of LH and Dhh has a profound effect on the transition of SLC into PLC ([Li et al., 2017](#)). In the *Pdgfra* ablated testis there are indications that some transition of SLC into PLC occurs but that proliferation of the latter cells is severely hampered leading to a nearly complete absence of LC at day 42 postpartum ([Gnessi et al., 2000](#)). In vitro experiments support this assumption as addition of PDGFA to SLC increased their proliferation.

In addition to the factors described above there is a considerable number of paracrine factors mainly of Sertoli cell origin that in concert with LH, and to a lesser extent FSH, affect the process of SLC and PLC growth and differentiation. Among these factors are *Lif*, *Scf*, *Egf*/Transforming growth factor α (*Tgfa*), *Igf1*, and *Fgf2*. To keep the process of LC development in abeyance, locally produced inhibitors of this developmental process have also been identified, including *Amh*. As indicated, proliferation of PLC contributes largely to the final size of the mature ALC population. Next to the already mentioned factors, *TGFB* has been identified as an inhibitor of PLC proliferation. The stimulatory effects of LH on PLC development are thought to be indirect and autocrine by the stimulation of PLC *IGF1* production. LC proliferation is inhibited in *Igf1* knockout mice, despite the presence of LH.

SLC expression of the transcription factor *Coup-tfII* has been implicated to be required for LC lineage commitment. *Coup-tfII* further promotes the maturation of PLC into ILC (reviewed in [Teerds and Huhtaniemi, 2015](#)). The final differentiation of ILC into mature ALC is highly dependent on the presence of LH. Whether LH directly influences this process or via stimulating *Igf1* gene expression and synthesis, is at present not clear.

Clinical Aspects

Hypogonadism

Suppressed testicular, that is, LC production of T causes a condition termed hypogonadism. Its symptoms entail those of androgen deficiency, including reduced (oligozoospermia) or absent (azoospermia) spermatogenesis, poor sexual function, and reduced muscle mass, hair growth and bone mass (osteoporosis). Hypogonadism can be due to failure of the testis tissue (primary) or to failure at the hypothalamic-pituitary level to secrete gonadotropins (secondary). It may appear at different times of life ranging from fetal life until old age, and it is usually caused by a distinct organic failure in function at some level of the HPT axis, for example, mutation of genes regulating hypothalamic function, gonadotropin secretion or testicular steroidogenesis. Milder functional failure of testicular function in older age (andropause, late-onset hypogonadism) is a contentious topic, because it does not fulfill many diagnostic criteria of genuine organic hypogonadism, and opinions vary about its clinical significance and treatment options.

Aging of Leydig Cells

There is a slight gradual decline in LC function upon aging, which is caused combined by a defect in the gonadotropin control of LC function and by intrinsic alterations of LC. In aging males there is a reduction in LC number, LH efficacy to stimulate steroidogenesis, LC sensitivity to LH, all of them implicating a reduced effectual LH drive as cause for decreased T levels. Whether this decline is an inevitable physiological phenomenon or a pathophysiological response to aging-associated health problems is still poorly understood. In support of the latter are the findings that old men in perfect physical condition show marginal decline in serum T, and that the reversal of obesity in aging men reverses T suppression ([Huhtaniemi, 2014](#)). Aging per se is considered to cause primary LC hypofunction. Secondary hypofunction of the testis, regularly reported in older men (low T and inappropriately normal or low LH levels), is largely independent of age and associated with obesity and comorbidities.

In many strains of rodents the age-related decrease in T production is mainly due to reduced GnRH release from the hypothalamus, attenuating pituitary LH release, as well as reduced LC response to LH ([Wang et al., 2017](#)). Reproductive aging in the Brown Norway rat, in contrast to most other rodent species, is solely of gonadal origin, which makes it a good model of human male aging. Detailed analysis of this model has shown that decreased LH-stimulated cAMP production and cholesterol transport into the mitochondria are of particular importance in the decreased T production of aged LC. One key mechanism in LC aging is apparently the metabolic generation of free radicals ([Wang et al., 2017](#)), whereby aging cells are in a chronic state of oxidative stress as a consequence of an age-related imbalance. In line with these observations it has also been shown that decreased steroidogenesis is associated with a deficiency in autophagy of aged rat LC.

Leydig Cell Tumors

LC hyperplasia is common in various disorders of testicular function but its mechanism is still poorly understood, although excessive LH stimulation may be involved ([Rajpert-De Meyts et al., 2000](#)). A term “LC adenoma” is used when the nodule size exceeds several-fold the diameter of a seminiferous tubule. LC hyperplasia and adenomas can be induced in rodents by estrogens, gonadotropins and many chemical compounds. LC tumors account for 1%–3% of testicular neoplasms in humans, and about 20% of them occur between 5 and 10 years of age, in conjunction with precocious T production and puberty. Under these conditions, androgen secretion is gonadotropin independent, and therefore LH and FSH remain low in spite of external signs of puberty. In adults with LC tumors, gynecomastia is a common finding (caused by T conversion to estrogen), but the tumor’s excessive androgen secretion has rarely notable effects. LC tumors are always benign in children, whereas in adults 10%–15% of them are malignant. The latter are usually hormonally inactive and resistant to conventional chemotherapy and irradiation.

A special case of LC tumors is formed by excessive adrenocorticotropin (ACTH) secretion in poorly controlled 21-hydroxylase deficiency (congenital adrenal hyperplasia, CAH) or Nelson syndrome (postadrenalectomy status), where the direct ACTH stimulation may lead to development of hyperplastic LC nodules, termed testicular adrenal rests.

Mutations Affecting LC Function

Several mutations and polymorphisms have been discovered in the key genes regulating LC development and function in humans, and their phenotypes have been confirmed in genetically modified mice (reviewed in [Teerds and Huhtaniemi, 2015](#); [Tremblay, 2015](#)). Inactivating mutations of the *LH β -subunit* (*LHB*) cause hypogonadotropic hypogonadism with LC hypoplasia and lack of sexual maturation after birth. *LHCGR* mutations cause a more severe phenotype with complete lack of masculinization (46, XY DSD) and pubertal development in a genetic male, because in this case FLC fail to respond to hCG stimulation. Mutations in *INSL3* and its receptor gene are rare causes of cryptorchidism ([Ivell et al., 2017](#)). Another tropic hormone whose mutation causes LC hypofunction is osteocalcin. *Androgen receptor* mutations are detrimental for the maturation of ALC and several steroidogenic enzyme genes. Concerning steroidogenesis, mutations of *StAR* and most of the genes involved in T biosynthesis have been found as causes of LC hypofunction, DSD, testicular dysgenesis and hypogonadism. Furthermore, there is plethora of transcription factors whose mutations cause LC hypoplasia and hypoandrogenism, such as *SF1* (*NR5A1*), *DAX-1*, *GATA4*, *ARX*, *COUP-TFII*, *C/EBP β* , *NUR77*, *DHH*, *HHAT*, and *MAMLD1*. Somatic mutations of regulatory genes have been found in LC tumors.

Leydig Cells as a Target for Male Contraception

Despite the efforts for decades a modern male contraceptive is still not available ([Chao and Page, 2016](#)). The task is formidable because of multiple reasons, including the obstacles imposed by male biology, minimal tolerance for side-effects, societal attitudes and poor funding opportunities. The most advanced form today is the hormonal approach, where inhibition of LC production of T and suppression of the high intratesticular concentration of T, necessary for the maintenance of spermatogenesis, are the targets. The goal can be achieved by treatment with T (alone or in combination with progestin), whereby the circulating concentration of T becomes slightly elevated, increasing consequently the negative feedback inhibition of gonadotropin secretion. The suppression of gonadotropins, in particular of LH, brings about cessation of LC T production and the androgen support of spermatogenesis. Numerous clinical studies have been carried out on this regimen with encouraging results. Azoospermia has been achieved in many studies with over 90% efficacy. Unfortunately, the development of this method is currently at near standstill because of expected and unexpected side-effects (depression, altered libido, acne, weight gain), lack of public funding and the reluctance of pharma industry to invest in further research.

Leydig Cell Toxicology

The function of FLCs, including humans, has recently received increased attention because of the fears of these cells being a sensitive target for demasculinizing effects of endocrine disrupting chemicals (EDCs) through interference with their androgen production and action during pregnancy ([Wang et al., 2017](#)). While there is a plethora of studies in vivo and in vitro on antiandrogenic and/or estrogenic inhibitory effects of EDCs (mostly phthalates and bisphenol A) on FLCs in various animal models, there are large species differences in their actions. The findings of EDC effects on rat, mouse and human FLC T and INSL3 production are rather conflicting, and it is difficult to decipher salient conclusions from the existing data. Interestingly, the mechanisms whereby EDCs affect LC function appear to be very similar to the aging-related alterations of LC function, that is, decreased mitochondrial cholesterol transport and reduced cAMP response to LH.

Besides the conflicting results between various animal models, another caveat in the field of EDC research is whether positive findings have been made using doses that have relevance for real-life exposure from the environment. The existence of EDCs as mixtures in the environment further complicates the situation. The field is currently polarized between proponents and skeptics with respect to the importance of EDC health hazards. An interesting conclusion in a review on EDCs ([vom Saal and Hughes, 2005](#)) was that harmful effects are likely to be found in research sponsored by governmental funding, whereas no harm is found when the funding came from industrial sources! Much more research is undoubtedly needed before the issue of harmful EDC effects will be settled.

Conclusions

- Distinct populations of LC exist in the testis during a male's life span, including fetal, neonatal (in humans), and adult LC.
- The differentiation and function of human and rodent FLC is initially independent of LH/CG stimulation.
- Human FLC become subsequently highly dependent on hCG for T production, while the rodent FLC are, besides pituitary LH, responsive to a plethora of other hormones and paracrine factors.
- The complex regulation of LC from stem through PLC and ICL to mature LC has been unraveled by recent research.
- The main function of LC at all ages is to produce androgens (and INSL3) for the maintenance of spermatogenesis and extragonadal androgenic and anabolic effects, mainly through tropic stimulation of LH, but also by numerous auto- and paracrine factors.
- LC function slightly decreases during aging, but most aging men remain eugonadal.
- Clinically significant LC hypofunction results in hypogonadism which involves suppressed spermatogenesis and extragonadal androgen actions (e.g., sexual dysfunction).

- LC function and sexual maturation are affected by rare mutations of genes regulating LC functions.
- LC may give rise to benign and malignant tumors.
- LC and sexual development and function may be targets of deleterious effects of EDCs.

Leydig Cells: Fetal to Aged Testes

Introduction

In mammals, two distinct populations of Leydig cells have been identified: fetal Leydig cells (FLCs) and adult Leydig cells (ALCs). These cells appear sequentially from development through adulthood, with the appearance of FLCs preceding that of ALCs (Fig. 1). The high levels of androgens produced by the fetal testis are required for the proper development of the male reproductive system, brain masculinization, and the expression of key enzyme activities later in life. In the rat, testosterone production declines with the loss of the FLCs, reaching a nadir at 2–4 weeks postpartum, and then gradually increases to high levels with the development of ALCs from Leydig stem cells present in the neonatal testis (Fig. 2). Once formed, the ALCs rarely divide or die. With aging, there is a progressive decline in testosterone production by ALCs, resulting in reduced serum testosterone levels. Androgens are involved in many systems in the male in addition to reproduction, including cardiovascular, skeletal, and muscular. Consequently, it is critical to understand the regulation of Leydig cell formation and the causes and consequences of their aging.

Fetal Leydig Cells

During mouse gestation, fetal progenitor cells that express steroidogenic factor 1 (SF-1) have been identified as the cells that give rise to the FLCs (Fig. 1). FLC differentiation is promoted by platelet-derived growth factor A (PDGFA) and desert hedgehog (DHH), and suppressed by the Notch pathway (Barsoum et al., 2013). Knockout of DHH has been shown to result in the development of reduced numbers of FLCs, with the adults lacking Leydig cells. These results suggest a possible relationship between the FLCs and ALCs. However, the observations that FLCs and ALCs have different gene expression profiles and appear sequentially, and that few FLCs are seen in the adult testis, suggest that FLCs and ALCs represent distinct populations of cells arising from distinct types of fetal progenitor cells (Barsoum et al., 2013).

In the rat, FLCs produce testosterone by gestational day (GD) 15.5, with production increasing markedly thereafter and reaching a peak just prior to birth (Fig. 2). LH is not required either for the development of FLCs or for their initial testosterone production. The FLCs ultimately express LH receptor and respond to LH stimulation. The testosterone produced by the FLCs and its metabolite dihydrotestosterone (DHT) are required for the morphogenesis of organs of the urogenital system, including the epididymis, vas deferens, seminal vesicles, prostate, penis and scrotum, and later in gestation for penile growth and testicular descent into the scrotum. Testosterone also regulates testis development. Testosterone and its metabolites DHT and estradiol have programming effects on neural function, driving brain masculinization. Though some FLCs persist in the adult testis, it is unlikely that they contribute significantly to testosterone production in the adult (Barsoum et al., 2013).

Development of Adult Leydig Cells From Stem Cells

ALCs develop from stem cells (stem Leydig cells; SLCs) present in the early neonatal testis (Fig. 1). Four distinct stages of ALC development have been identified: SLCs, progenitor Leydig cells (PLCs), immature Leydig cells (ILCs), and ALCs

Fig. 1 Developmental timelines of testicular Leydig cells. Cells from the coelomic epithelium in the urogenital ridge form a common adrenogonadal primordium at gestation day (GD) 9. Between GD10–11, gonad and adrenal primordia separate. Between GD10.5 and 12.5, SRY expression drives Sertoli cell differentiation and male gonad formation. Between GD12.5 and GD13.5, fetal Leydig cells are formed from SF1+/POD1- progenitor cells, with increasing numbers seen from GD12.5 to 15.5. SF1+ cells that remain undifferentiated due to POD1 expression are believed to be the precursors of the stem Leydig cells that ultimately differentiate to progenitor, immature and ultimately adult Leydig cells.

Fig. 2 Diagram of increasing testosterone production in the fetus by the fetal Leydig cells, reduction testosterone production postnatally with the loss of the FLCs, and then increasing testosterone production with the formation of ALCs from SLCs after birth.

(Ge et al., 2006). The SLCs are spindle-shaped cells surrounding the seminiferous tubules and also associated with the vasculature in the interstitial compartment of postnatal 7 rat testes. The cells were isolated and purified by virtue of their expression of PDGFR- α but not LHR or the steroidogenic enzyme 3β -hydroxysteroid dehydrogenase (3β -HSD). In vitro, the SLCs cells were found able to maintain their phenotype and to self-renew indefinitely, stimulated to do so by DHH, FGF2, PDGFBB, activin, and PDGFAA, and inhibited by TGF β (Chen et al., 2017). When cultured in medium containing LH, PDGF, thyroid hormone and IGF-1, SLCs were induced to differentiate into cells that expressed 3β -HSD and ultimately produced testosterone. The SLCs also were shown to be capable of differentiating into 3β -HSD-expressing Leydig cells in vivo after their injection into the interstitial compartment of adult rat testes from which Leydig cells had been eliminated by injection of the Leydig cell toxicant ethane dimethanesulfonate (Ge et al., 2006).

By postnatal day 14, some among the SLCs give rise to spindle-shaped PLCs in vitro. In contrast to the undifferentiated SLCs, PLCs express the Leydig cell markers 3β -HSD and LHR, and produce low levels of testosterone. By postnatal day 28, the PLCs form a population of ILCs that increases to ~ 13 – 14 million, accounting for half of the ALCs in the adult rat testis. The testosterone metabolite 5α -androstane- 3α , 17β -diol rather than testosterone is the major steroid produced of ILCs. The ILCs undergo one to two divisions and further differentiate, producing the full complement of ~ 25 million ALCs by postnatal day 56. The ALCs are terminally differentiated cells that are characterized by their production of high levels of testosterone (Fig. 2). At 90 days, Leydig cell testosterone production is 150 times greater than that produced by PLCs, and 5 times greater than by ILCs (Ge et al., 2006).

Adult Leydig Cell Function and Aging

The primary function of Leydig cells in the adult is to produce testosterone. Leydig cell testosterone production involves cholesterol transport into mitochondria, pregnenolone formation in the mitochondria, and conversion of pregnenolone into testosterone by enzymes of the smooth endoplasmic reticulum. Luteinizing hormone (LH), secreted by the pituitary gland in response to gonadotropin-releasing hormone (GnRH) from the hypothalamus, initiates this process by stimulating Leydig cell cAMP production which, in turn, stimulates cholesterol transfer into the mitochondria. The latter is the rate-determining step in testosterone formation. Cholesterol transport involves the actions of steroidogenic acute regulatory protein (STAR), translocator protein (18 kDa; TSPO), and other proteins of the transduceosome (Miller and Bose, 2011; Rone et al., 2012).

In both humans and rodents, serum testosterone levels decline progressively with aging (Chen et al., 1994; Wang et al., 1999). Age-related decreases in serum testosterone levels result from reduced testosterone production by aging Leydig cells, not from a reduction in cell numbers. Reduced serum testosterone, whether in young or older men, is associated with a number of metabolic and quality-of-life changes, including decreased lean body mass, bone mineral density, muscle mass, libido and sexual function, increased adiposity, cardiovascular disorders, and altered mood (Bhasin and Basaria, 2011; Hwang et al., 2011). In hypogonadal men in whom there are deficiencies in central stimulation (hypogonadotropic hypogonadism, Kallman's syndrome), serum testosterone can be elevated by administering LH or hCG, or indirectly with clomiphene or aromatase inhibitors. However, hypogonadism in most patients is not the result of central deficiencies, but rather decreased responsiveness of the Leydig cells to LH. In these men, attempts to increase Leydig cell testosterone production and thus serum testosterone levels through LH stimulation typically are not effective.

Testosterone replacement therapy (TRT) often is used to raise serum testosterone levels (Gruenewald and Matsumoto, 2003). The availability of methods by which to elevate testosterone levels has made TRT accessible and palatable to men. However, recent

studies suggest increased risk of cardiovascular disease resulting from TRT (Xu et al., 2013). There also are reports suggesting that TRT might increase the risk of prostate cancer (Bosland, 2014). Additionally, TRT in most men will suppress LH, resulting in reduced intratesticular testosterone concentrations and thus in spermatogenesis suppression, making this an inadvisable approach for men wishing to father children (Hwang et al., 2011; Ramasamy et al., 2011).

In Brown Norway rats, as in men, testosterone levels decrease with age despite unchanging LH levels (Chen et al., 1994). The culture of Leydig cells isolated from old rats with LH was shown to result in testosterone production that was reduced significantly below its production by LH-stimulated young cells. However, culturing the old cells with dibutyryl cAMP, thus bypassing LH receptor-G protein stimulation, resulted in elevated testosterone production that in fact was comparable to its production by LH-stimulated young cells. These studies suggest that reduced testosterone production by aging Leydig cells results from the relative insensitivity of the cells to LH caused by deficient signal transduction. Knowledge of the steps and mechanisms in testosterone formation has made it possible to consider the use of pharmacological means to increase serum (and intratesticular) testosterone by stimulating the Leydig cells themselves. TSPO, involved in translocating cholesterol to the inner mitochondrial membrane, comprises 2% of the outer mitochondrial membrane (Culty et al., 2002). TSPO drug ligands have been used in clinical studies to increase neurosteroids in men with neurological and psychiatric disease symptoms (Northdurfter et al., 2012). We observed that activation of TSPO by specific drug ligands resulted in increased T production by aged Leydig cells both in vitro and in vivo, and thus in elevated serum T levels (Chung et al., 2013). Such studies hold promise for providing new means by which to increase serum testosterone levels without administering LH-suppressive testosterone.

Summary

Fetal Leydig cells produce the high levels of testosterone in the fetus that are required for the establishment of the male reproductive system and for subsequent steroidogenic and reproductive functions of the adult. Fetal Leydig cells are lost beginning early in postnatal life, and as a consequence testosterone production declines. Testosterone levels begin to increase as adult Leydig cells develop from the stem Leydig cells of the neonatal testis. There is progressive decline in testosterone production by the adult Leydig cells as they age, associated with a number of metabolic and quality-of-life changes. TRT is available and widely used to elevate serum testosterone levels, but is not without risk. Knowledge of the mechanisms involved in testosterone formation has made it conceivable to use pharmacological means to increase serum (and intratesticular) testosterone by stimulating the Leydig cells themselves, thus avoiding TRT.

Peritubular Myoid Cells in Testis

Ryan P Thompson, Eric E Nilsson, and Michael K Skinner, Washington State University, Pullman, WA, United States

Background

In men of good health, there are layers of flattened cells and extracellular matrix (ECM) proteins that make up the wall of the seminiferous tubules. The cells located along this wall are peritubular myoid cells, which have smooth muscle-like properties (Mayerhofer, 2013). Peritubular myoid cells fall under the classification of a mesenchymal/stromal cell type. They reside immediately exterior to the extracellular matrix (ECM) that is at the basal surface of the Sertoli cells in seminiferous tubules (Skinner, 1989). Peritubular cells have been found in all mammalian species looked at thus far, although there are differences in the numbers of layers of peritubular cells (Skinner and Griswold, 2005).

Peritubular myoid cells possess the ability to contract and use this feature to transport immotile sperm. Peritubular cells produce growth factor receptors that respond to endothelins (ET), vasopressin and platelet-derived growth factor beta (PDGF β), in turn leading to contractility of the seminiferous tubule (Skinner, 2005). Human testicular peritubular cells (HTPCs) manufacture extracellular matrix components such as the proteoglycan decorin, thought to influence paracrine signaling between testicular cells. Peritubular cells along with extracellular matrix proteins form the walls of the seminiferous tubules. There are distinct differences in peritubular cells between humans and rodents. In a human, there are several layers of stretched out, thin, spindle-shaped peritubular cells and extracellular matrix (ECM) proteins that form the wall of the seminiferous tubule. However, in a laboratory rodent this same wall is constructed of a single peritubular cell layer with a minimal extracellular matrix (ECM). No matter the model, mature peritubular cells express markers of smooth muscle-like cells. This expression of smooth muscle actin is induced around the age of sexual maturity in primates primarily by androgens. Androgens are thought to play a critical role in the differentiation process that occurs in peritubular cells. After expression of smooth muscle actin is evoked, removing the androgen stimulation appears to have no effect (Mayerhofer, 2013). Peritubular myoid cells (PMCs) also provide structural support to seminiferous tubules. It is worth noting that the seminiferous tubular wall compartment in men who are subfertile or infertile with impaired spermatogenesis is often abnormal. Testicular tubular fibrosis, which is easily diagnosed by thickened deposits of extracellular matrix (ECM), is known as a clear sign of male infertility. Testicular tubular fibrosis and morphological alterations to peritubular cells, such as hypertrophy, likely suggest that particular capacities of peritubular cells, such as hormonal and contractile functions, are modified. Figs. 1 and 2 clearly illustrate the differences between a healthy layer of peritubular cells in comparison to that in an infertile man (Mayerhofer, 2013).

Peritubular cells continue to divide throughout a lifetime and therefore need growth regulation even after adulthood (Skinner, 1989). Early in embryonic development during the time of testis determination, peritubular cells originate from mesenchymal cells within the mesonephros next to the developing gonad. Mesonephric cells travel into the gonad and drive seminiferous cord formation along with Sertoli and primordial germ cell aggregates to form precursor peritubular cells that are part of the outer layer of what will become the seminiferous tubules (Skinner, 2005).

Sertoli Cell–Peritubular Cell Interactions

Previous studies suggest both peritubular cells and Sertoli cells produce Transforming growth factor α (TGF- α), which is capable of acting as an EGF (epidermal growth factor)-like substance to trigger peritubular cell growth. The assumption is made that TGF- α possibly has an important role in controlling testis cell growth and mediates a peritubular cell–Sertoli cell interaction. Conversely, transforming growth factor- β (TGF- β) is a growth factor that can act as an inhibitor in these interactions. Transforming growth factor- β (TGF- β) is a family of gene products that promote cell differentiation and inhibit cell division, in particular in TGF α responsive cells. TGF- β originates from peritubular cells as well as Sertoli cells. TGF- β was found to have no major effects on Sertoli cell function or growth. However TGF- β blocked the ability of TGF- α to promote peritubular cell proliferation. TGF- β was also found to induce peritubular cells to form colonies in cell culture and heighten the production of extracellular matrix components. As a result, TGF- β is thought to likely play a part as a chemotactic agent for peritubular cells and impact seminiferous tubule morphogenesis (Skinner, 1989).

Peritubular cells express activin, a product that has the ability to act on Sertoli cells to influence prepubertal Sertoli cell proliferation. Peritubular cells express heregulins also known as neu differentiation factors (NDF), such as NDF α and NDF β , which have the ability to act through receptors located on Sertoli cells (Skinner, 2005). In addition to these factors, peritubular cells express leukemia inhibitory factor (LIF), which has the ability to act on early-stage spermatogenic cells and likely also Sertoli cells (Piquet-Pellorce et al., 2000). Several other potential paracrine factors produced by peritubular cells have the ability to influence Sertoli cell function (Table 1). The connection between Sertoli cells and peritubular cells and their ability to regulate one another was discovered as a result of androgens not being able to promote peritubular cell differentiation on their own, rather, the presence of gonadotrophin-stimulated Sertoli cells was necessary as well. A combination of Leydig cell and peritubular cell interactions with Sertoli cells have been noted as being essential to Sertoli cell development and function (Skinner, 2005).

Fig. 1 Testicular morphology and composition of the tubular wall in the adult human testis in health (normal spermatogenesis; A and C) and disease (infertility B and D). (A) The tubular wall (*arrows*) is normally an inconspicuous compartment, in which only few nuclei of peritubular cells are visible in hematoxylin and eosin (H&E)-stained sections. Note the close proximity of the tubular wall to the tubular compartment (TC) containing Sertoli cells and germ cells and to the interstitial compartment (ISC) with Leydig cells. Bar: $\sim 30\ \mu\text{m}$. (B) In samples from infertility patients, the tubular wall is often enlarged, deposits of ECM are seen, and both elongated and round peritubular cell nuclei (*arrows*) are seen in the thickened wall. H&E stain. Bar $\sim 30\ \mu\text{m}$. (C and D) Immunohistochemical identification of mast cells containing tryptase, in a normal testis (C) and in a testicular biopsy of an infertility patient (D). Note that in the section of the normal testis, only one mast cell is present in the interstitial compartment (C). In contrast, in the section from the infertility patient, several mast cells are seen and accumulate in the wall of seminiferous tubules (*arrows* in D) Bar $\sim 60\ \mu\text{m}$. From Mayerhofer, A. (2013). Human testicular peritubular cells: More than meets the eye. *Reproduction*, 145, R107–16.

Studies have shown that both Sertoli cells and peritubular myoid cells express androgen receptors (Norton et al., 1994). It was found that the effect of androgens on Sertoli cells was greater in Sertoli cell aggregates in co-cultures containing peritubular cells as opposed to Sertoli cell preparations without the presence of peritubular cells. Therefore, it's postulated that the stimulatory effects of peritubular cells on functions of Sertoli cells in co-culture, specifically to sustain the production of androgen binding protein (ABP), are affected at least moderately by component(s) manufactured by peritubular cells and secreted into the medium. Peritubular cells accumulate androgens and react to testosterone *in vivo* in addition to *in organ culture*. Peritubular cells in culture, when stimulated by androgens, secrete substances that have the capability to maintain elevated rates of androgen binding protein production by Sertoli cells. As postulated, an experiment confirmed basal rates of androgen binding protein were raised by the presence of peritubular

Fig. 2 Electron microscopy of human peritubular cells in the wall of seminiferous tubules. (Top) In the healthy adult, several layers of thin, peritubular cells (*arrows* at nuclei) and ECM form the wall of seminiferous tubules. Bar: ~3 μm . (Bottom) The morphology of the tubular wall of an infertility patient reveals cellular hypertrophy (*arrow* at nucleus) and increased ECM (*asterisk*). Bar: ~4 μm . Table 1 Major Sertoli cell and peritubular cell paracrine regulatory products

<i>Potential paracrine factors</i>	<i>Site production</i>	<i>Site action</i>	<i>Action/proposed function</i>
PModS	Peritubular	Sertoli	Paracrine regulatory agent
TGF- α	Peritubular	Sertoli	Growth stimulation EGF-like
TGF- β	Both	Both	Growth inhibition
TGF-I	Both	Both	Maintenance cell growth/differentiation
NDF α /NDF β	Peritubular	Sertoli	Increase differentiation
LIF	Peritubular	Gonia/Sertoli	Growth stimulation
Activin	Peritubular	Sertoli	Growth stimulation
NT3	Sertoli	Peritubular	Embryonic chemotactic factor
bFGF	Sertoli	Peritubular	Growth stimulation

cells. When peritubular cell levels were raised to 30%, a nearly proportional increase in androgen binding protein production was noted, leading scientists to speculate that the increase was connected to the heightened levels of peritubular cell factors released. It is important to note that co-culture of Sertoli cells with peritubular cells assists in maintaining the production of androgen binding protein (ABP) with or without the presence of follicle stimulating hormone (FSH). Peritubular cells lack the ability to synthesize androgen binding protein (Skinner and Fritz, 1985).

After Sertoli cell ablation in an adult mouse testis, a single peritubular myoid cell layer with a standard appearance was found to encompass the majority of seminiferous tubules up to 1 year following ablation. After 1 year, there was loss of integrity in the

connective tissue of either the peritubular or interstitial regions. These findings indicate that seminiferous tubule remodeling occurs over a long period of time. It is postulated that the remodeling process incorporates several different cell types such as peritubular myoid and interstitial cells. Findings appear to indicate that, although the presence of the basement membrane is able to preserve peritubular myoid cell fate for many months following Sertoli cell ablation, the Sertoli cells are vital to maintaining routine peritubular myoid cell function. Findings indicate that peritubular myoid cells are largely responsible in regulating immune cell access to the seminiferous epithelium. It was noted that where macrophage invasion of the tubule transpired, peritubular myoid cell morphology was changed, however, it is not known whether this was responsible for causing the macrophage invasion or just a repercussion (Rebourcet et al., 2014).

Studies have revealed that when Sertoli cells were not present the peritubular myoid cells were not able to form a functional barrier to biotin. This result points towards Sertoli cells being able to support the barrier properties of peritubular myoid cells. Findings also indicate that when Sertoli cells are not present, the peritubular myoid cells and underlying extracellular matrix are adequate for keeping macrophages out of most tubules. Therefore, it is thought that peritubular myoid cells mediate the immune privilege of the seminiferous tubules (Rebourcet et al., 2014).

Developmental studies have revealed that during fetal and neonatal life Sertoli cells are crucial to maintaining seminiferous tubular structure and the preservation of peritubular myoid cell phenotype. However, as an animal enters puberty Sertoli cells are not necessary to retain seminiferous tubule structure as well as peritubular myoid cell differentiated function, since at this stage the basement membrane is capable of supporting these functions. Previous developmental studies have indicated that Sertoli cells are fundamental at all ages to the upkeep of all germ cell populations, including spermatogonia (Rebourcet et al., 2014).

Signaling Pathways

Peritubular cells generate the paracrine factor known as PModS that is responsible for mediating mesenchymal–epithelial interactions and regulating Sertoli cell functions necessary for the process of spermatogenesis. PModS has been observed to stimulate cGMP levels in Sertoli cells and sustain heightened cGMP levels in culture for as long as 5 days. There are two different isoforms of PModS that have been isolated, PModS (A) and PModS (B), although it appears there is little difference between the two and they share the same apparent biological activities. Findings suggest that PModS (A) is a processed form of PModS (B). PModS has the ability to affect tyrosine phosphorylation of Sertoli cell proteins, and blockage of tyrosine phosphorylation puts an end to the activity of PModS on Sertoli cells. The gonadotrophin follicle stimulating hormone (FSH) and the testicular paracrine factor PModS promote actions affiliated with a more differentiated state of the Sertoli cell, such as the secretion of androgen-binding protein and transferrin. PModS has been shown to raise Sertoli cell cGMP levels, however, cGMP does not directly influence the actions of PModS. Signaling mechanisms such as cAMP levels, calcium uptake, and phosphatidyl inositol hydrolysis, were not affected by the paracrine factor PModS. Findings suggest that PModS potentially shapes an important phosphorylation event. PModS has been observed to have an impact on the tyrosine phosphorylation of a Sertoli cell protein(s) following a 72-h treatment. It is not yet determined whether these tyrosine phosphorylations are correlated with the increased differentiation of the cell and/or influence the actions of PModS (Norton et al., 1994).

Androgen Receptors

Peritubular cells react to androgens by heightening the production of PModS (Anthony and Skinner, 1989). Mice with a targeted disruption of the androgen receptor gene (Ar) in peritubular myoid cells saw a continuous loss of spermatogonia. This finding led researchers to suggesting that peritubular myoid cells depend on testosterone (T) action to generate factors influencing the spermatogonial stem cell in its niche. The addition of testosterone to adult mouse peritubular myoid cells in vitro was found to result in considerable spikes in the amount of glial cell line-derived neurotrophic factor (GDNF) mRNA and protein. The findings revealed that testosterone has the ability to control the production of glial cell line-derived neurotrophic factor by peritubular myoid cells in vitro and support the hypothesis that peritubular myoid cells have a major effect on the microenvironment of the niche and spermatogonial stem cell maintenance (Chen et al., 2014).

Lgr4 Role in the Maintenance of Spermatogenesis

A study in mice found that Lgr4 is selectively expressed in peritubular myoid cells. Knockout of Lgr4 leads to germ cells going into arrest at meiosis I, followed by apoptosis. The levels of androgen receptor, alpha-smooth actin and extracellular matrix proteins were substantially lowered in Lgr4 mutant (Lgr4^{1-/-}) mice. Sertoli cell nucleus position as well as functional protein expression differed in Lgr4^{1-/-} mice. Wnt/β-catenin signaling was disabled in the peritubular myoid cells of Lgr4^{1-/-} mice. After Wnt/β-catenin was reactivated through breeding with Apc^{min/+} mice or by Gsk3β inhibitor treatment, the deficiency of Lgr4 was incompletely rescued. These findings as a whole indicate that peritubular myoid cell Lgr4 signaling by means of Wnt/β-catenin is critical to spermatogenesis (Qian et al., 2013).

Fig. 3 Diagram of testis cell associations and the interactions between cells. From Skinner, M. K. (1989). Peritubular myoid cell–Sertoli cell interactions which regulate testis function and growth. *Perspectives in Andrology*. 175–182.

Connection to Male Fertility

Spermatogonial stem cells (SSCs) are essential for lifelong spermatogenesis in men. In men, human testicular peritubular myoid cells (HTPCs) are thought to partly responsible for regulating the overall testicular microenvironment through the actions of secreted proteins. Findings support the concept of human peritubular cells playing a critical role in spermatogonial stem cell (SSC) niches in men. Human peritubular cells have been shown to supply several neurotrophic factors, such as glial cell line derived neurotrophic factor (GDNF). GDNF is essential for the renewal of spermatogonial stem cells (SSCs) throughout species. GDNF is a factor that comes from both peritubular cells and Sertoli cells. Due to the proximity of peritubular cells to spermatogonial stem cells, peritubular cells by the way of GDNF may regulate spermatogonial stem cells in a paracrine manner. Findings have contributed to the idea that peritubular cells of the seminiferous tubule wall are important to the spermatogonial stem cells (SSC) niche in the human testis. Peritubular cells are also thought to be a part of the general regulation of testicular functions by producing elements which have the ability to affect Sertoli cells and Leydig cells (Wen et al., 2016). Fig. 3 indicates the relationship between three of the major cell types found in the testis (Skinner, 1989). In summary, peritubular myoid cells have a critical function for testis biology and it is the cellular interactions of all cell types that is required.

Glossary

Cadherin Transmembrane proteins that participate in cell-cell adhesion.

Coelomic epithelium The inner layer lining the body cavity and is immediately adjacent to/covering the gonad.

Coelomic vessel The embryonic precursor to the main testicular artery, located on the side of the gonad adjacent to the coelomic epithelium and farthest from the mesonephros.

Days post coitus (dpc) Embryonic day of development with the timing of conception designated as day 0.

Elastin An extracellular protein that is highly elastic and allows tissues to resume their shape after stretching/contracting.

Extracellular matrix A broad category of molecules secreted from cells into the intercellular space to provide structural and biochemical support to the tissue.

Filopodia A cellular structure made of thin projections of cytoplasm supported by bundles of actin filaments.

Germ cell A cell that gives rise to gametes (i.e., sperm and oocytes).

Lumen The cavity/channel within a tube.

Mesonephric vascular plexus The network of small blood vessels present within the mesonephros during embryonic development.

Mesonephros The temporary kidney of the mammalian embryo which is replaced by the metanephros.

Morphogenesis The biological process of changing the shape of an organism or tissue.

Seminiferous tubules Curved tubules within the lobes of the testis where meiosis and spermatogenesis occur.

Somatic cell Any cell other than a germ cell or gamete.

Splice variants The product of alternative splicing in which different combinations of RNA exons can be used to yield a variety of protein products from a single gene.

Testis cords The male embryonic sex cords that are the precursor to seminiferous tubules.

Undifferentiated A cell that is still multi-potent and has not attained its final cell identity.

Vascular endothelial cells The cells that make up the inner lining of all blood vessels in the cardiovascular system.

Introduction

Creating a functional mammalian testis is a very involved procedure with many critically important steps. One of the most crucial events during this process is the migration of vascular endothelial cells (i.e., cells that make up the inner lining of blood vessels) into the developing gonad. Without the migration of endothelial cells into the gonad from the nearby mesonephros (i.e., embryonic kidney) there would be no patterning or reorganization to form the seminiferous tubule structures that are necessary for testis functionality (Buehr et al., 1993). This article will take you through the sequence of events involved in this remarkable migratory event that shapes the testis and will use rodents as the main examples. As you will see, these vascular cells follow a series of actions. The migrating endothelial population waits for an invitation, stays on the designated paths as it moves, communicates with its hosts, and is necessary for testis tissue functionality.

The migration of cells from one organ to another can be discussed as three main events. (1) Cells receive a signal creating an impetus to pack up and move. They lose their adhesion to the surrounding cells and change their cytoskeletal dynamics so that they now have the ability to migrate. (2) Cells actively migrate into a new tissue. In the case of endothelial cells migrating into the testis, they do so along specific paths to section the testis into avascular domains. (3) The cells must then integrate into their new home and begin to function as part of the tissue as a whole. This occurs as the disparate vascular cells reconnect and form new blood vessels. Throughout this process, the cells of the gonad secrete signaling molecules telling the endothelial cells when and where to migrate. The endothelial cells also secrete signaling molecules and communicate with the developing testis. Together, they control testis morphogenesis during a critical period of development (Fig. 1).

The Nature of the Vascular Endothelial Cell

Blood vessels are multilayered structures. They contain an inner layer of endothelial cells surrounding the lumen through which blood passes. These endothelial cells are connected to each other primarily via a transmembrane adhesion protein called

Fig. 1 Vascular endothelial cells follow specific steps during migration from the mesonephros into the developing testis.

VE-cadherin (vascular endothelial cadherin) in structures called adherens junctions (Lampugnani et al., 1995). The smallest blood vessels, capillaries, are made of single endothelial cells wrapped around the lumen and a surrounding basement membrane (secreted extracellular matrix). Larger blood vessels contain a one-cell-thick layer of multiple connected endothelial cells, thicker layers of extracellular matrix (for stability), layers of elastin (for flexibility in response to blood pressure changes), and smooth muscle cells (to control the diameter of the vessel). Based on the types of cell-cell adhesion molecules besides VE-cadherin that are expressed in the endothelial cells, the inner lining of some blood vessels will have more/larger gaps in between cells and thus greater permeability than in other vessels. The endothelial lining of blood vessels is thus crucial in controlling what molecules and cells are exchanged between the blood and surrounding tissues. As you will see, these vascular endothelial cells can also be a driving force in developmental processes and provide crucial cell-cell communication.

Setting the Stage for Vascular Migration Into the Testis

Prior to sex determination, the mammalian gonads have the potential to become either ovaries or testes. The earliest developmental events are the same for both male and female embryos. First, an area of undifferentiated tissue (coelomic epithelium) thickens and forms the urogenital ridge, which will give rise to both the reproductive and urinary tracts (Fig. 2). However, this newly formed gonad precursor only includes somatic cells, not germ cells (the future sperm and oocytes). The primordial germ cells then begin to migrate into the early gonad from the hindgut region of the embryo. These changes occur before the critical window when the sex determination switch is flipped to either testis or ovary development. That critical time is at approximately 10.5 *dpc* (days post coitus, i.e., day of embryonic development) in most mouse lines that have been researched or 12 *dpc* in the rat. The human window of sex determination is approximately between days 41–44 post ovulation (Hanley et al., 2000). As you can see in Fig. 2, however, the migration of the germ cells into the gonad continues to occur during and after sex determination.

Fig. 2 Migration of mesonephric endothelial cells into the testis occurs immediate after the critical sex determination window.

The distinction between male and female development is made by the presence or absence of a Y chromosome containing the *SRY* gene (Sex-Determining Region of Y). The expression of *SRY* during a brief but critical window activates a complex network of gene expression and cell-to-cell signaling that sets the events in motion to cause male reproductive tract development and to suppress female tract development. The main genetic players in this network are well conserved between humans and mammalian research models like the mouse. The initiation of the male signaling network is a prerequisite for the vascular endothelial cell migration that is so important in forming the appropriate testis structures (Capel et al., 1999; Martineau et al., 1997; Raymond et al., 1999).

Once the male gene expression patterns have been established in the somatic cells of the testis, another gene is turned on to produce a secreted signaling molecule: Vascular Endothelial Growth Factor A (VEGFA). This protein is involved in creating blood vessels in a wide variety of biological contexts including the development of various organs and tumor growth. The VEGFA protein is produced and released from somatic cells in the early testis and diffuses away until it makes contact with its receptor (i.e., KDR; Kinase Insert Domain Receptor) on endothelial cells in the neighboring mesonephros tissue. This is a well-studied event in rodents, but embryonic development studies in humans have not been undertaken; however, somatic cells of adult human testis biopsies do secrete VEGFA. While there are variations (splice variants) of VEGFA of different sizes with that can have differences in function, the main result of VEGFA binding to its receptor on an endothelial cell is to promote cell proliferation and migration (Bott et al., 2006; Baltes-Breitwisch et al., 2010; Ergün et al., 1997).

Endothelial Cell Migration

When VEGFA from the developing testis first makes contact with endothelial cells within the mesonephros, those vascular endothelial cells are fully connected to each other in a network of capillaries called the mesonephric vascular plexus. These existing blood vessels break apart in response to the VEGFA so that individual cells can migrate into the nearby gonad tissue. In an embryo that is XX and therefore developing a female reproductive tract, the mesonephric vascular plexus remains intact and endothelial cells do not migrate into the ovary during this window in development (11.5–13.5 dpc in the mouse). Instead, the ovary gains vasculature by promoting branching and extension of nearby vessels into the ovarian tissue rather than dissolving intact vessels as in the XY embryo. This major sex-specific vascularization event of the testis is distinct in that it requires the dissolution of blood vessels, the migration of separated cells, and then the reassembly of blood vessels from those cells within the testis. However, the population of endothelial cells does not migrate all at once. Vascular cells trickle into the developing testes over a period of approximately 24 h using the rodent developmental timeline (Fig. 2) (Coveney et al., 2008).

The mechanics of this migration are similar to actively migrating cells in other contexts. First, the cells lose their connections (cellular adhesions) to each other and change from a flattened, extended shape to a more amorphous shape with multiple long extensions called filopodia (Fig. 3). These cell shape changes have been directly observed by fluorescent microscopy in endothelial cells within mesonephros and gonad tissue in culture dishes. The way that the cells actually migrate has not been directly studied within the mesonephros/testis context, but studies of other types of endothelial cells have shown that VEGFA can directly affect the cytoskeleton (Waltenberger et al., 1994; Li et al., 2005). In order to achieve active migration in a specific direction, the cytoskeleton (especially actin fibers) on the side of the cell that is closest to the source of the VEGFA has to be stabilized and extended. The cytoskeleton on the side farthest from the source of the VEGFA is less stable and the actin fibers will be depolymerized more quickly. In this way, the cell effectively “crawls” towards the target tissue by gradually extending the “leading edge” and retracting the “trailing edge.”

One fascinating and not yet fully understood aspect of the vascular endothelial cell migration is that the cells stay on specific paths as they travel through the testis. The general direction of migration (towards the far side of the testis) is established by a diffusion gradient of VEGFA, but the way that this broad signal is narrowed to separate paths through the tissue is not known. However it

Fig. 3 Endothelial cell migration requires changes in cell-cell adhesion and cytoskeleton dynamics in response to a diffusion gradient of a signaling molecule such as VEGFA.

is accomplished, it is a well-established observation that the endothelial cells travel through specific parts of the testis and not others, separating the testis into approximately 10 avascular domains (Coveney et al., 2008).

Partitioning the testis into domains separated by newly re-formed blood vessels made of the immigrated endothelial cells is a key step in developing testis morphology. If the vascular endothelial cell migration occurs but the re-formation of blood vessels in the testis is experimentally prevented by inhibiting the vascular cell-cell adhesions, then testis cords (the precursors to seminiferous tubules) cannot form at all. The formation of testis cords requires the reorganization of the cells of the testis so that the germ cells are surrounded by layers of somatic cells (Sertoli cells and peritubular myoid cells) with areas between the testis cords containing other interstitial cells (including the Leydig cells and blood vessel branches). If VEGFA signaling is inhibited, the migratory event does not take place at all and testis cords do not form (Bott et al., 2006; Baltés-Breitwisch et al., 2010). This vascular endothelial cell migration event is thus important not only for supplying circulation to the testis but also for initiating structural changes that must occur for future testis functionality. This migration and the testis changes that result from it cannot be directly studied in human embryos, so knowledge of these events depends on rodent embryonic studies. However, given the strong similarities between human and rodent testis morphology and the conservation of the genes involved in testis development, it is reasonable to suspect that these developmental events occur in a similar manner (Combes et al., 2009; Bott et al., 2006; Tilmann and Capel, 1999).

Integration Into the Testis Community

The re-formation of blood vessels from migratory endothelial cells to separate the avascular domains of the testis occurs between 12.25 *dpc* and 12.5 *dpc* in the mouse (Combes et al., 2009). So, the reestablishment of endothelial cell-cell adhesion is coordinated and relatively quick. Further growth and development of the testis is accompanied by blood vessel branching and extension of vessels into the interstitial space between testis cords. This ensures adequate circulation to all areas of the testis.

A key role that the vascular endothelial cells play once they have arrived in the testis is to communicate with the surrounding tissue by secreting a signaling protein called platelet-derived growth factor (PDGF). This signaling protein from the endothelial cells interacts with somatic cells in the testis to promote their proliferation. If PDGF signaling is experimentally inhibited, testis cords do not form and vascularization of the testis can actually be inhibited even if endothelial cell migration occurs. Thus, the mere presence of vascular endothelial cells is not sufficient for testis cord morphogenesis. Instead, it is the cell-to-cell interactions between the endothelial cells and the somatic testis cells that are important (Cool et al., 2011; Uzumcu et al., 2002).

An additional cell-cell communication role that the endothelial cells must play is to recruit macrophages from outside the testis. Fetal macrophage migration into the newly forming major testicular artery (known as the coelomic vessel) starts as early as 10.5 *dpc* in the mouse and is dependent on endothelial cell presence. These macrophages appear to promote tissue remodeling to aid in testis vascularization and testis cord formation (DeFalco et al., 2014).

Finally, beyond the vital contributions to testicular development and morphogenesis, the importance of vasculature to the adult testis cannot be overlooked. The reproductive capabilities of the adult male will depend on the circulation of nutrients and oxygen into the testis, thermoregulation via the blood, incoming signals from the pituitary gland to regulate hormone and sperm production, and output of steroid hormones to interact with the hypothalamus and pituitary gland. All of these functions require adequate vascularization of the testis (Fig. 4).

Fig. 4 Role of vasculature in adult testis.

Conclusion

While it is just one cell type among many involved in testis development and function, the vascular endothelial cell is a very necessary contributor. This population of cells begins as a vascular network in the mesonephros and then migrates into the testis to establish an entirely different vascular network. The endothelial cell migration depends on the signal, VEGFA, coming from the somatic cells of the early testis. Endothelial cells respond to the signal by disengaging their adhesions with each other and changing their cytoskeleton so that they can actively migrate towards the source of the signal. As they migrate into the testis, they do so along designated paths through an as-yet-unknown mechanism. They form the main future testicular artery (the coelomic vessel) on the far side of the testis, and also partition the testis into approximately 10 avascular domains. This partitioning is required for testis cord formation. However, as the endothelial cells are migrating they are simultaneously secreting their own signal: PDGF. This protein interacts with the somatic cells of the testis in order to promote their proliferation and coordinately establish the testis cords. Without either VEGF signaling or PDGF signaling, the testis cords cannot form. Additionally, the vascular endothelial cells recruit macrophage migration into the testis to further assist in testis cord formation. All of these efforts together result in testis morphogenesis and vascularization. The vasculature itself will then be crucial in adult testis physiology to circulate nutrients and signaling molecules into and out of the tissue.

Introduction

The male reproductive capacity of adult mammals depends on the ability of their testes to produce viable spermatozoa, as well as, an adequate level of several hormones including testosterone necessary for the development of libido and reproductive functions. The formation of the male gamete within the seminiferous tubules is a highly complex process, in preparation from embryonic life (migration of primordial germ cells), fetal, neonatal and prepubertal (production of gonocytes, prespermatogonia) which develops from puberty and continues throughout life through the renewal and division of spermatogonia stem cells. Differentiating germ cells are distributed in a highly organized manner as they move between adjacent Sertoli cells, from the basal to the adluminal compartments of the seminiferous tubules following the successive developmental stages: (i) A-spermatogonia, (ii) B-spermatogonia, (iii) primary spermatocyte, (iv) secondary spermatocyte, (v) spermatid and, (vi) spermatozoon (Fig. 1).

The general organization of spermatogenesis is essentially identical in all mammals and can be divided into three main phases, each of which leads to the production of a distinct category of germ cells:

(1) the mitotic phase which corresponds to the proliferation of spermatogonia. During this phase, spermatogonia produce two types of diploid cells: stem cells, necessary for the renewal of their own stock, and spermatogonia that proliferate in cascade to generate differentiated spermatogonia. These latter generate in their final phase primary (preleptotene) spermatocytes,

(2) the meiotic phase characterized by two successive cell divisions without intermediate DNA synthesis and which results in the formation of haploid spermatids. In all species, this phase is divided into five successive stages called leptotene, zygotene, pachytene, diplotene and diacinese,

(3) the spermiogenic phase which corresponds to the metamorphosis of each spermatid into a spermatozoon.

Table 1 summarizes the main cellular types and morphological transformations along the spermatogenic process. At the end of these three phases, the spermatozoa are released into the lumen of the seminiferous tubules, a process called spermiation. The morphology features of germ cells and somatic cells of the seminiferous epithelium, tissular organization and synchronic distribution along spermatogenesis have been evaluated over the years in many species (see notably, Clermont, 1963; De Kretser and Kerr, 1988; Russell and Ettlin, 1990). The main studies involving human spermatogenesis were performed around the 60s by Clermont and colleagues, who described GCs, spermatogonial kinetics and cell renewal. This article will concentrate on the morphological and structural features of the male germ cells in mammals with special reference to humans.

Fig. 1 Germ cell organization within a seminiferous tubule (transverse section) with corresponding spermatogenic phases.

Table 1 Summary of the mammalian germ cell types along the spermatogenic process**Mitotic phase**

A proportion of spermatogonia enter mitosis and, after five mitosis, become type B spermatogonia, which divide into primary spermatocytes

A1 Spermatogonia → A2 Spermatogonia → A3 Spermatogonia → A4 Spermatogonia
→ (Intermediate spermatogonia) → B Spermatogonia → Primary spermatocytes

Meiotic phase

Primary spermatocytes enter meiosis. The first meiotic division leads to secondary spermatocytes and the second division to the haploid round spermatids

Primary spermatocytes ($2n$ chr/ $4n$ DNA) → Secondary spermatocytes ($2n$ chr/ $2n$ DNA) → Round spermatids ($1n$ chr/ $1n$ DNA)

Spermiogenesis

The spermatogenic step where spermatids differentiate into spermatozoa:

- DNA is associated with the protamines nuclear basic proteins and become highly condensed
- The acrosome, tail and the midpiece containing mitochondria are formed
- Most of the cytoplasm is eliminated

Round spermatids → Elongating spermatids → Elongated spermatids → Spermatozoa

Spermatogonia

In all mammals, spermatogonia are defined as constituting the mitotic compartment of spermatogenesis including stem, undifferentiated and differentiating cell types, possessing distinct morphological and molecular characteristics. Even though the real nature of the spermatogonial stem cell and its regulation is still debated the general consensus holds that in steady-state spermatogenesis the stem cell compartment needs to balance differentiation versus self-renewal.

Spermatogonia derived from the differentiation of gonocytes. In adult mammals, spermatogonia are very few in number and located in the periphery of the seminiferous tubules, leaning against the *lamina propria*, in contact with the Sertoli cells. In primates, such as monkey and man, there are three morphologically distinct subpopulations of spermatogonia: dark type A (Ad spermatogonia), pale type A (Ap spermatogonia) and type B (B spermatogonia). In humans, Ad spermatogonia represent the reserve of stem cell, and Ap spermatogonia correspond to a population of cells intended to ensure the renewal of the stock of the progenitor cells of the spermatogenic process. The Ap and Ad spermatogonia are considered to be the counterpart of the mouse undifferentiated spermatogonia and type B that of the mouse differentiating spermatogonia (Fig. 2). Ad spermatogonia does not divide under normal conditions of testicular function. On the other hand, Ap spermatogonia divide by mitosis to maintain their own cellular stock and for each of them, generate 2 B spermatogonia, which themselves divide by mitosis and enter into meiosis. In humans, only one generation of B spermatogonia has been characterized, whereas there are four in the macaque.

Indeed, if the general pattern of spermatogonial organization and their differentiation (from stem cell to differentiated spermatogonia) is globally identical in mammals, the spermatogonial system presents many differences from one species to another in primates, and between primates and rodents (Ehmcke and Schlatt, 2006; Boitani et al., 2016; see Fig. 2).

**Fig. 2** A schematic diagram of different cell subtypes within the spermatogonial compartment in the mouse, monkey and man.

The ability to distinguish different classes of spermatogonia is critically dependent on the morphological characteristics of the nuclei as revealed on stained preparations of transverse sections of seminiferous tubules by conventional light microscopy.

In humans, from a morphological point of view:

- The Ad nuclei contain a deeply stained dust-like chromatin with a characteristic large central vacuole-like cavity, which, at the electron microscopic level, appears as a chromatin rarefaction zone; close to the nuclear membrane one or more nucleoli are found.
- In contrast, the ovoid Ap nuclei contain a fine, homogenous and weakly stained chromatin, one or two nucleoli lying close to the nuclear membrane and no vacuoles.
- B spermatogonia exhibit the features described for other species, though the human cells are somewhat smaller. Type B spermatogonia are characterized by large clumps of intensely stained condensed chromatin under the nuclear membrane of an ovoid nucleus contrasting with a fine granulated chromatin in the rest of the nucleus.

Spermatogonia as observed by conventional light microscopy have a poorly stained cytoplasm. Studies of whole-mounts of seminiferous tubules have demonstrated that they remain connected by intercellular bridges such that large numbers are effectively linked together. Using the PAS reaction, glycogen is found in Ad spermatogonia.

At the electron microscope level (observations by transmission electron microscopy, TEM), the basal position of spermatogonia within the epithelium and their extensive contact with the basal membrane of the tubule are clearly evident. The extent of this contact decreases in B spermatogonia which will eventually lose all contacts with the basal membrane to become preleptotene primary spermatocytes (see below). All types of spermatogonia are characterized by a relatively electron-lucent cytoplasm and a paucity of cytoplasmic organelles. Because of incomplete cytokinesis during mitosis, spermatogonia remain connected by intercellular bridges, 2–3 μm in width usually not containing organelles or microtubules.

Attempts have been made to classify spermatogonia at the TEM level, notably in humans. Most investigators agree that it is possible in humans to identify the type A dark, type A pale and type B spermatogonia, though intermediate forms may occur. The classification is based on: (i) the nuclear and nucleolar features, (ii) the presence of aggregations of mitochondria, (iii) the presence or absence of glycogen granules, and, (iv) the presence of crystalloids (in human spermatogonia).

- Ad spermatogonia: oval shaped nucleus with electron translucent region compatible with the nuclear vacuole observed by light microscopy, small nuclei adjacent to the nuclear membrane, mitochondria lying close to the nucleus with a cristae generally extending transversally across the matrix, abundant rough endoplasmic reticulum, Golgi complex poorly developed, presence of glycogen granules, often aggregated, presence of crystalloids (=collections of fibrils and tubules aligned along the long axis of the structure up to $\sim 3 \mu\text{m}$ in length).
- Ap spermatogonia: less contact with the basal membrane, finely granulated homogeneous chromatin, nuclei without vacuoles, amorphous peripherally placed nucleoli, paucity of organelles, few mitochondria generally isolated or by pairs, glycogen granules rarely observed, presence of crystalloids.
- B spermatogonia: the spermatogonia having the least contact with the basal membrane, peripherally placed chromatin less prominent than by light microscopy (due to the thin sections), nucleolus centrally placed, mitochondria scattered without the intermitochondrial material observed in type A spermatogonia.

In both nonhuman and human primates, some authors suggest the existence of so-called A transition spermatogonia, having no unequivocal morphological characteristics of either Ad or Ap spermatogonia. In the rat, Type A isolated (Ais) is believed to be the stem cell, whereas in humans, it is unclear which Type A spermatogonia is the stem cell.

Spermatocytes

The cells in the spermatogenic process that are involved in meiosis are the primary and secondary spermatocytes (Fig. 3). Spermatocytes are the cells originating from the last spermatogonial division (B spermatogonia) from which spermatids, then, spermatozoa with half the chromosome complement of the original progenitor cell will be generated following the meiotic phase of spermatogenesis. The process of meiosis involves two cell divisions, the first involves primary spermatocytes generating after the diakinesis secondary spermatocytes which in turn are involved in the second meiotic division producing the haploid spermatids. Because of the long duration of the prophase of the first division (for example, 24 days in humans), primary spermatocytes are found on tubule sections, in every stage of spermatogenesis (and, for a given stage different types of spermatocytes may be observed). By contrast, because the second meiotic division progresses rapidly (lasting about 5 h in humans), secondary spermatocytes are rarely observed on tubule sections.

Primary Spermatocytes

The primary spermatocytes arising from B spermatogonia lose contact with the basal membrane of the seminiferous tubule and migrate in direction of the adluminal compartment by transiently breaking the tight junction complexes of the Sertoli cells. The primary spermatocytes exhibit the features of the first meiotic division in terms of nuclear morphology. As the spermatocytes pass through meiotic prophase they become larger and the appearance of the nuclear chromatin alters, reflecting the condensation

Fig. 3 Summary of the meiotic stages with the corresponding cellular types and subtypes.

and movement of the chromosomes as they prepare for meiotic division. The meiosis phase involves several types of spermatocytes ranging in size (from small, for example, preleptotene, to very large, for example, late pachytene) and presenting typical morphological features for each of the five stages of the prophase of the first meiotic division, preleptotene, leptotene, zygotene, pachytene, and diplotene which are clearly distinguished under the optical microscope. Peripherally located nucleoli are frequently seen in primary spermatocytes. TEM reveals they consist of extremely electron dense aggregations of granules. The cytoplasm of primary spermatocytes is more electron-dense than that of spermatogonia and contains evenly scattered polysomes and ribosomes. Features of rough and smooth endoplasmic reticulum are rare. However, during the progression of the prophase, the Golgi complex close to the nucleus gradually enlarges. Thanks to its high resolution power, TEM has revealed the existence of a subcellular structure, the synaptonemal complex in the nuclei of primary spermatocytes form a number of species. The synaptonemal complex consists of two lateral elements that appears as electronic dense fibrils equidistant from a central element consisting of a delicate linear region of increased electron density (its appearance and evolution is presented below with the different cellular and subcellular morphological features at each stage of the prophase). The number of synaptonemal complexes is equal to the number of bivalents. Though the synaptonemal complex provides the framework necessary for synapsis, it is thought that the recombination modules are the vital components in the crossing-over of genetic material.

Primary spermatocytes are joined to each other by intercellular bridges similar to those found between spermatogonia. They are separated from adjacent Sertoli cells by distinct intercellular spaces that are modified in some regions by desmosome-like structures.

Preleptotene stage

They present a spherical nucleus with an aspect similar to those of B spermatogonia, though smaller. Notably, they lack any chromosomal elements. They are termed preleptotene spermatocytes in reference to the S phase, the preleptotene phase of DNA synthesis, the process by which each chromosome when it condenses is composed of a pair of chromatids, the total of DNA content representing twice the diploid content.

Leptotene stage

During this stage, the chromosomes become apparent as single fine threads. TEM has revealed they are attached at each extremity to the nuclear membrane (giving the “bouquet” aspect) by “attachment plaques” which in fact are the lateral element of the synaptonemal complexes assembling and appearing at this stage. Though at this stage the chromatid pairs are present, they are not visible and will not do so until later in prophase. At this stage, the X and Y chromosomes appear associated with the dense body of the sexual vesicle, a special condensation of chromatin fibrils.

Ovoid mitochondria aggregated in groups of two or three, with an electron dense material similar to that seen in spermatogonia are observed at this stage (and at the subsequent zygotene stage).

Zygotene stage

This stage is characterized by the thickening of the chromosomal elements that begin the process of pairing termed synapsis. Pairing of the elements of the synaptonemal complexes begins at this stage.

Pachytene stage

The long pachytene stage begins with the completion of synapsis and is associated with further thickening and shortening of chromosomes. During this stage, exchanges of chromosome material between maternal and paternal homologous chromosomes occur by crossing over. At the points of crossing over, bridges (chiasmata) are seen in variable numbers. Depending on the chiasmata, different aspects of the chromosomes can be observed. Nuclear and cytoplasmic growth of pachytene spermatocytes result in these cells becoming the larger of all germ cells. Fully formed synaptonemal complexes are observed by TEM at this stage.

Diplotene stage

Desynapsis occurs during this phase. The paired chromosomes partially separate (jointly to the synaptonemal complexes disassembly) but remain joined at their chiasmata. Subsequently, the chromosomes further shorten, then detach from the nuclear membrane during the diakinetin phase, the stage where the two chromatids of each chromosome can be seen.

Diakinesis to telophase

Diakinesis is rapidly followed by the disappearance of the nuclear membrane, the appearance of the spindle and the alignment of the homologous chromosome pair with the metaphase plate, followed by the migration of each part of the chromosome pair toward the opposite poles of the spindle during the anaphase. The telophase completely separates the chromosomes and produces the secondary spermatocytes.

Secondary Spermatocytes

These are the cells that undertake the second meiotic division which begins after a very short interphase without DNA replication takes place. The phases are typical of any cell division (pro-, meta- ana and telophase 11) in that one chromatid from each pair (making up each chromosome) migrates to each daughter nucleus. The secondary spermatocytes have the haploid number of chromosomes, though their DNA content is still diploid so that when they complete meiosis, the resulting spermatids have both an haploid chromosomal content and DNA content.

Secondary spermatocytes are round cells with a size ranging between the primary spermatocyte and the round spermatid size and a greater nucleo-cytoplasmic ratio. They are situated close to the lumen of the tubule (see figure) and their nucleus contains an homogeneous chromatin network throughout which large globular chromatin masses are dispersed. Nucleoli centrally positioned are often observed. Light and electron microscopy reveal the presence of intercellular bridges between adjacent secondary spermatocytes similar with those found for other germ cell categories. TEM reveals scattered features of endoplasmic reticulum arranged concentrically around the nucleus, a prominent Golgi complex containing vesicles with electron-dense granules and dispersed mitochondria with dilated intracristal spaces.

Spermatids

Spermatids are the products of the second meiotic division and lack the ability to divide. Their progressive transformation takes a unique, complex, and lengthy process (for example, 23 days in humans) of morphological and functional differentiation termed spermiogenesis which sees the early spermatids with a usual cellular aspect (a round cell with a central nucleus surrounded by homogeneously distributed organelles) at the time of their formation to be metamorphosed into highly specialized polarized cells: the spermatozoa. Under physiological conditions, the transmission of the paternal genome to the oocyte at the time of fertilization requires the development of the acrosomal system, the rearrangement of the nucleus and perinuclear structures, the assembly of the flagellar structures, the elimination of the vast majority of the cytoplasm concomitant with a reorganization of cell organelles. These changes will be briefly reviewed using human spermiogenesis as a model. The major morphological features of spermiogenesis are common to all species but, details in the morphogenetic process and the resulting sperm morphological characteristics vary for each species since different morphological features may depend on different species-specific genetic determinants. The mammalian sperm morphogenesis is a continuum sequence of complex morphological changes which has been subdivided for descriptive purposes into successive steps, the number of which varies according to the species (rat: 19, mouse:16, ram, bull, boar: 15, baboon: 10). In humans, six steps are distinguished according to the shape of the nucleus, the aspect of the chromatin and the general morphology of the cell (**Fig. 4**): Sa, Sbl (round/early spermatids), Sb2, Sc (elongating/intermediary spermatids) Sd1, Sd2 (elongated/mature/late spermatids).

The first step corresponds to the small round spermatid produced by the second division of meiosis. The round spermatid, smaller than the secondary spermatocyte presents a central spherical nucleus with a diffuse chromatin containing one or more nucleoli lacking a clear fibrillary center (subsequently, in spermatids in elongation, the nucleolus fragments before disappearing completely), a well developed Golgi apparatus, adjacent centrioles, dispersed mitochondria lying peripherally close to the plasma membrane and microtubules (the future components of the axoneme) visible at the periphery of the cytoplasm.

Fig. 4 Spermiogenesis steps in humans. Modified from Holstein, A. F. (1976). Ultrastructural observations on the differentiation of spermatids in man. *Andrologia* 8 (2), 157–165.

In addition the chromatid body, a regular electron-dense mass, can be observed adjacent to the Golgi complex. During the evolution of the round spermatid, the nucleus and the Golgi vesicle attached to it rotate to a position opposite to that of the developing flagellum.

Spermatids are located in the adluminal compartment of the seminiferous tubule, in close contact with Sertoli cells. Spermatids at different steps of differentiation may be observed in the same tubule cross section (see Fig. 1).

Formation of the Acrosome

The evolution of the acrosomal material, as revealed by PAS staining, has been one of the criteria used to identify the steps of the spermatid differentiation by light microscopy. The acrosome morphogenesis is generally described according to four subsequent distinct morphological phases which can be easily distinguished by TEM: the Golgi, the cap, the acrosome and the maturation phases. These four phases exhibit a general pattern but display variations in different species. Soon after the formation of the early round spermatid, the Golgi apparatus assembles the elements necessary for the formation of the acrosome: several small secretory-like granules rich in glycoproteins form on the trans face of the Golgi stacks. These proacrosomic granules coalesce to give a single larger acrosomic vesicle which associate with the nuclear membrane and tightly adheres to it to become an acrosome. This early acrosome show an electron-dense core and a less dense cortex by TEM. The Golgi apparatus continues to contribute glycoproteins to the acrosome by means of numerous small carrier vesicles. The lighter peripheral portion of the acrosome expands at the surface of the nucleus taking the shape of a cape covering at this step ~half of the nuclear surface. The tight adhesion of the acrosome membrane to the nuclear membrane is due to the presence of proteinaceous substance that later condense to form part of a rigid capsule or perinuclear theca that covers the nucleus of spermatozoa. With the displacement of most of the cytoplasm toward the caudal pole of the spermatid, the Golgi apparatus separates from the acrosome, regresses and finally disappears. At later steps of spermiogenesis and as the nucleus takes its species-specific shape, the acrosome also condenses and conforms to the changing form of the apex of the nucleus shape. The final size and shape of the acrosome varies from one species to another (for example, small in man and important in the guinea pig for example and paddle-shaped in human vs. hook-shaped in rodents).

Nuclear Elongation and Chromatin Condensation

During spermiogenesis, the central nuclei of the round/early spermatids elongate and condense their chromatin to become the main polarized component of the head compartment with an acquired species-specific shape (piriform in man,

flattened or paddle-shaped in ram, bull, and dog, falciform in rodents). A remodeling of the chromatin from its nucleosomal form to a thread-like filamentous form is first observed, then, the chromatin filaments thicken, become coarse and aggregate into compact masses that coalesce to form a dense chromatin mass (as illustrated in Fig. 4). It is established that the first morphological transformation is associated with histones modifications and loss, the second being linked to the presence of TP1 and TP2 transition proteins. Late in spermiogenesis, when the chromatin condensation has occurred and the definitive shape of the nucleus has been acquired, the transition proteins are replaced by arginine and cysteine-rich protamines conferring to the nucleus an extreme compaction protecting the genome. Several studies have indicated a specific arrangement of chromosomes in round and intermediate spermatids which could be involved in the formation of the male pronucleus.

Assembly of the Flagellar Structures

During the early steps of spermiogenesis, the pair of centrioles migrates toward the nucleus. One out of the two centrioles triggers the formation of the axoneme consisting of a bundle of microtubules, arranged in a 9 + 2 pattern (the intracytoplasmic axoneme is observed precociously from step 2 in humans). As the centrioles move toward the nucleus, they pull with them the plasma membrane, which then forms a double-wall sleeve around the growing axoneme. In the elongated spermatid, electron-dense material is deposited around the centrioles and forms a striated collar that characterizes the neck portion of the tail. The sperm tail is not similar to other flagellum or cilium since it associates a periaxonemal component including two specific cytoskeletal elements, the outer dense fibers and the fibrous sheath which are deposited along the central axoneme soon after it terminates its growth. The mitochondria peripherally close to the plasma membrane in round spermatids migrate toward the forming tail as the manchette appears in elongating spermatids. Following the sliding of the annulus (which derives in part from the chromatoid body) along the axoneme and the periaxonemal structures, the mitochondria line up in an orderly manner along the dense fiber between the neck and the annulus. Later during spermiogenesis, the mitochondria condense and dispose themselves side by side and tip to tip in a spiral manner. This mitochondrial sheath delimitates the midpiece of the length whose length is species-specific.

Cytoplasm Elimination

The gradual elimination of the cytoplasm from early spermiogenesis until the formation of mature spermatids is an evident observation in seminiferous tubule sections by light microscopy and TEM. In the most advanced phases of spermiogenesis, nearly 90% of the spermatid cytoplasm is eliminated. This progressive elimination takes place in two stages: (i) the first is continuous via the tubulobulbar complexes, the cytoskeleton-related membrane structures developing at sites of intercellular attachment in the mammalian seminiferous epithelium, a component of the sperm release mechanism (at apical junctions between Sertoli cells and spermatids the structures internalize adhesion junctions and evaginations of the elongating spermatids penetrating inside the Sertoli cells), (ii) the second occurs at the time of spermiation when the main part of the cytoplasm that remains after the reduction of tubulobulbar complexes is eliminated in the form of corpuscles called residual bodies, which are captured and phagocytosed by Sertoli cells. These residual bodies contain most of the spermatid organelles, lipids and polyribosomes, and their phagocytosis probably plays is known to play an important role in regulating the functioning of the Sertoli cell and in synchronizing the cycle of the seminiferous epithelium.

Transitory Organelles and Structures

Spermiogenesis is characterized by the presence of transient organelles whose role is unknown or not fully elucidated. Cytoplasmic microtubules anchored on the nuclear ring posterior to the acrosome constitute the manchette. The manchette displaces part of the cytoplasm with its organelles behind the caudal part of the nucleus and the nuclear ring also moves caudally. It is visible in the elongating spermatids and disappears well before the end of spermiogenesis. It consists of microtubules which form a sort of mitotic half-spindle arranged around the caudal region of the nucleus. The manchette, connected by a filamentary tract to the nuclear envelope and to the chromatin, could exert an external stress on the nuclear form, sliding gradually toward the base of the nucleus (Lehti and Sironen, 2016). The spindle-shaped body.

The chromatoid body located in the cytoplasm of round spermatids appears like a cluster of electron dense granules that presumably derives from the nuclear membrane, although its significance remains unknown. It contains actin, long half-life RNA, basic proteins, ribonucleoprotein particles as well as polysaccharides and cations.

Energetics of Spermatogenic Cells

Michael D Griswold, Washington State University, Pullman, WA, United States

© 2018 Elsevier Inc. All rights reserved.

Energy metabolism in the testis is governed by the unique structural and productivity issues of germ cell development (Griswold, 1993). First, since haploid gene expression can trigger immune responses the testis is an immune privileged tissue by virtue of tight cellular junctions between adjacent Sertoli cells. This barrier is one of the most restrictive in all of biology and results in the formation of a basal and an adluminal compartment. Transfer of metabolites required for energy production must negotiate this barrier. Second, the net outflow of cellular components into the germ cells and ultimately out of the organism is very high. Estimates are that human males produce 1000–1500 sperm per second throughout their reproductive lifetime. Third, Sertoli cells extend from the basement membrane to the lumen of the seminiferous tubules and encompass stacks of developing germ cells. The apical end of a Sertoli cell and germ cells near that location are too far from a capillary blood supply to be satisfied by a diffusion process. Finally, nearly all metabolic determinations made on a single cell type in the testis have been made in vitro where the environment is vastly different than when cells are in situ.

It appears from published research on isolated cells that the metabolic requirements of Sertoli cells and germinal cells are quite different. Cultured Sertoli cells from immature rats metabolize added glucose primarily to lactate that is externalized into the culture medium. These results have led to the concept that one of the “nurse cell” functions of the Sertoli cells is to predigest glucose to lactate for use by germ cells. RNA synthesis, protein synthesis and oxygen consumption in cultured germ cells is stimulated by added lactate. In vivo evidence for this concept is lacking and it has been demonstrated that many cells in culture may have an impaired citric acid cycle and produce copious amounts of lactate. Cultured Sertoli cells contain large lipid droplets and utilize oxidation of lipids as a major source of energy. In addition, cultured Sertoli cells can utilize glutamine and leucine as source of intermediates for the citric acid cycle. Sertoli cells metabolism is greatly affected by hormones such as FSH, testosterone and retinoic acid. These external agents act on Sertoli cells in cycles and modify the metabolism (Alves et al., 2013).

Germ cells appear to be primarily dependent on anerobic and aerobic carbohydrate metabolism. The spermatogonia that reside in the basal compartment of the testis have access to the blood supply and can use glucose as a source of ATP. Spermatocytes and spermatids reside in the adluminal compartment of the testis and can be some distance from the blood supply. These cells appear to rely on glycolysis and possibly lactate as a substrate. The metabolism of spermatozoa is better established since spermatozoa can be examined in their natural state as isolated cell types. Sperm have a very high glycolytic activity and require glucose for hyperactivated motility, capacitation and in vitro fertilization (Boussouar and Benahmed, 2004). Several genes encoding sperm specific forms of enzymes in the glycolytic pathway are expressed only in spermatids and spermatozoa. Sperm also have mitochondria confined to the mid-piece and therefore also undergo aerobic respiration and lipid oxidation (Rato et al., 2012).

The metabolic activities of the testicular cells and the relationships of these activities to cellular interactions still have many open questions. The problems associated with studies of metabolic pathways and their regulation in whole testis tissue are complex because of the multiple cell types. Since placing isolated cells in culture introduces other barriers to interpretation many questions remain unanswered. Fertility is clearly affected by energy production and reserves but the cellular mechanisms that link ATP production to spermatogenic cell development are not well understood. Questions relating to how Sertoli cells handle problems associated with high metabolic demand and low oxygen tension, or why and how germ cell metabolism appears to be changing during development remain (Griswold, 1993).

Spermatozoa and Sperm Structure

Jacques Auger, Paris Descartes University, Paris, France

Introduction

During spermiogenesis, haploid round spermatids displaying classical cellular anatomy—typically, a round cell with a central rounded nucleus surrounded by the usual cellular organelles—gradually turn into testicular spermatozoa, which, in the simplest terms, are made of a head and a flagellum composed of a proximal midpiece and a distal principal piece or tail. This morphogenetic process is characterized by complex biochemical and structural transformations of the cellular components required in order the sperm cells may fulfill their physiological function: moving progressively to transport a copy of the haploid genome to, and to interact with, the oocyte, thereby delivering its genetic information—along with a pool of proteins and RNAs—through fertilization. The vast majority of mammalian mature spermatozoa have a uniform morphology. By contrast, human spermatozoa, as observed on a stained semen smear, exhibit noticeable morphological variations in size or shape of the head and/or midpiece and/or tail. Those are the morphological and biometric characteristics of the spermatozoa retrieved from the uterine cavity or in the vicinity of oocytes, and thus those having a good fertility potential which have led to the definition of a morphologically normal human spermatozoon (World Health Organization, 2010).

This article will concentrate on the normal structure and substructures of physiological mammalian spermatozoa, using primarily the normal human spermatozoa as a model.

General Features of the Mammalian Spermatozoon

As it can be easily observed on stained and smeared semen samples by light microscopy, mammalian spermatozoa have a polarized organization following three major subcellular regions: the sperm head, the midpiece and the principal piece of the flagellum that can be typically observed by various microscopical approaches (Fig. 1). However, sperm cells from different mammalian species exhibit modifications of this basic structural pattern. For example, the shape of the head varies from one species to another (e.g., slightly flattened in humans and falciform in rodents). Also, the overall length of mammalian spermatozoa is species specific and varies considerably, for example $\sim 50\text{ }\mu\text{m}$ in boar $\sim 60\text{--}70\text{ }\mu\text{m}$ in human and $\sim 90\text{ }\mu\text{m}$ in bull. Its volume is very reduced compared to that of the oocyte, for example, $30\text{ }\mu\text{m}^3$ in the bull, that is, $1/20000$ of the volume of the cow's egg.

The main morphological features of the ejaculated sperm cell are established at the end of the spermiogenetic process so that ejaculated spermatozoa are morphologically identical to testicular spermatozoa though only the ejaculated sperm are functionally mature following the biochemical and molecular alterations undergone during their transport through the epididymal duct. The spermatozoon, like other cells, is totally enclosed in a lipoprotein plasma membrane containing glycoprotein particles and covered by a glycoprotein cell coat. The lipid and glycoprotein components are distinct according to each sperm compartment delimitating surface domains that are crucial for sperm functions. For example, the equatorial segment of the sperm plasma membrane is involved in the sperm oocyte interaction.

Morphologically normal (= potentially competent) human spermatozoa observed by conventional light microscopy on a smear properly stained have a regular oval head outline with a major axis measuring $3.7\text{--}4.7\text{ }\mu\text{m}$ and a minor axis measuring $2.5\text{--}3.2\text{ }\mu\text{m}$ with a major axis to minor axis ratio in the range $1.3\text{--}1.8$ (World Health Organization, 2010). The distinct acrosomal region (corresponding to both acrosomal and underlying nuclear structures) covers $40\%\text{--}70\%$ of the head surface, has a regular outline and a homogeneous texture. The postacrosomal region of the head has a regular outline and a homogeneous texture. The midpiece under conventional microscopy has a major axis $3.3\text{--}5.2\text{ }\mu\text{m}$ microns long in the prolongation of the major axis of the head, a regular contour, a homogeneous texture and a diameter of $0.5\text{--}0.7\text{ }\mu\text{m}$. The presence of residual cytoplasm of minimal size (one-third of the sperm head size) is not considered abnormal. The principal piece has a regular contour and a homogeneous appearance and it develops in the prolongation of the midpiece, measuring approximately $45\text{ }\mu\text{m}$ (about 10 times the length of the head) with a diameter decreasing gradually from the proximal part ($\sim 0.4\text{ }\mu\text{m}$) to the distal extremity of the flagellum.

Morphological and Structural Features of a Normal (Potentially Fertilizing) Human Spermatozoon as Revealed by Transmission Electron Microscopy (TEM)

The analysis of sperm morphology by conventional light microscopy on sperm smears is rather simple, but it has obvious technical limitations in term of resolving power and the ability to describe the internal substructures: the best looking spermatozoon by optical microscopy is not necessarily free of cellular or subcellular defects. By contrast, transmission electron microscopy (TEM), due to its resolving power and application on ultrathin sections, enables a fine and precise examination of all sperm substructures (Moretti et al., 2016) including the sperm internal organization (typically, the various substructures of the head compartment are well observed with a $\times 10,000\text{--}20,000$ magnification while fine observations of the axonemal components in a transverse section of the tail may necessitate $\times 100,000$ magnification and more).

Fig. 1 Morphologically normal human spermatozoa by various microscopic techniques. (A) Ultra-thin longitudinal and sagittal section of the half proximal part of a normal spermatozoon by transmission electron microscopy (TEM) showing a piriform profile of the head compartment, a well delineated acrosome covering most of the anterior part of the highly condensed nucleus containing some vacuoles, a transverse section of the proximal centriole and a segmented column in the neck region, a clear longitudinal image of the mitochondrial sheath delimiting the midpiece, and a less clear image of the axis of the flagellum containing the axoneme and the outer dense fibers and from the end of the midpiece, the peripheral fibrous sheath. (B) A scanning electron microscopy (SEM) image showing the typical regular paddle-shaped head compartment; (C) image obtained by the MSOME technique using light microscopy with Nomarski differential interferential contrast and $\times 6300$ final magnification showing clearly the limits of the head, midpiece and principal piece compartments and revealing the presence of a “vacuole” whose exact origin is still debated; (D) observation by optical microscopy of two morphologically normal spermatozoa with a pale homogeneous acrosome region (Shorr stained smear observed at $\times 1000$ final magnification). Central figure: a schematic drawing of a normal human spermatozoon with its different head and tail compartments and associated images of transverse sections by TEM, at the head level (highly condensed and regular nucleus surrounded by an acrosome with a less dense texture; a), midpiece level (axoneme in central position with the ODFs associated to the peripheral doublets surrounded by mitochondria; b), and principal piece (from center to periphery: central pair and peripheral doublets of the axoneme, associated ODFs and the fibrous sheath surrounded by the plasma membrane, LC: longitudinal; c: column).

Sperm Head

At the end of the spermiogenetic process the late/mature/elongated spermatid has acquired a fully developed acrosome usually covering the anterior part of the head where it caps the nucleus. It has lost most of its cytoplasm essentially in the head region and presents a noticeably reduced nuclear volume with a highly condensed nuclear material. The subsequent exfoliated testicular spermatozoon as the ejaculated mature spermatozoon presents an acquired species-specific head shape (i.e., piriform in humans, flattened or paddle shape in ram, bull and dog, and falciform in many rodents). The vast majority of the sperm head volume corresponds to the nucleus whose shape in most mammalian species follows the shape of the sperm head. The shape of the head/nucleus is species-specific and usually flattened dorsoventrally; the outline tends to be oval, ensiform or falciform. The remaining volume of the head is occupied by the acrosome, cytoskeletal elements and a residual cytoplasm. It is generally admitted that the acquisition of a “hydrodynamic” head shape with a highly condensed nuclear material may facilitate passive and active sperm transport in the male and female genital tract while the compaction of the chromatin compensating for the lack of DNA repair enzymes, allows safe transport of the male genome. At the end of the sperm journey in the female genital tract, the acrosome and nucleus, with the head part of the sperm plasma membrane represent the more important sperm head structures in the processes of sperm–oocyte interaction and fertilization.

Acrosome

Mammalian sperm acrosomes perform two principal exocytosis-dependent functions: (i) to serve as a site for the sequestration and release of proteins required for binding to and penetration of the zona pellucida and, (ii) to enable the sperm to fuse with the

oolemma. These functions are dependent upon the acrosome structure. The acrosome is a Golgi-derived secretory organelle with a cap-like structure covering the anterior part of the sperm head of most animal sperm. It is formed during an early stage of spermiogenesis and resembles the cellular lysosome, a bag-like structure that normally functions in intracellular digestive and defensive mechanisms. In mammals, the size and shape of the acrosome varies from species to species and depends on the morphology of the sperm head, it is determined, in part, by the underlying nuclear morphologies. The shape of the acrosome is quite variable between species, ranging from skull-cap/paddle-shaped (spatulate) in several larger mammals, including humans, to sickle-shape in rodents. In most mammalian species, the sac-like structure of the acrosome basically consists of two parts, the anterior and equatorial segments (Fig. 2). It is surrounded by an inner acrosomal membrane (IAM) that is laminated to the nuclear foundation and a fusogenic outer acrosomal membrane (OAM) that is closely apposed to the plasma membrane over the acrosome. The inner and outer acrosomal membranes surround the electron-dense content of the acrosome. The equatorial segment forms the posterior acrosomal margin where the IAM and OAM meet. The detailed structural composition, organization and the functions of the mammalian acrosome have been recently reviewed (Fléchon, 2016).

Nucleus

The nucleus contains the condensed chromatin carrying paternal genetic information with its typical homogeneous and dense aspect as observed on smears either by conventional microscopy or on sperm sections by TEM. This last technique also reveals small areas of uncondensed chromatin in the neck region and the presence of nuclear vacuoles—probable local defects of chromatin condensation—of irregular outline and size depending on the species, without surrounding membranes distributed at random in the dense nuclear material, particularly frequent and large in human spermatozoa. The homogeneous and dense textural characteristic of the mammalian sperm chromatin is linked with the histone–protamine exchange during the elongating phase of spermiogenesis which drastically modifies the structure and spatial organization of the chromatin. At the end of this process, the sperm chromatin is ~7 times more condensed than in the nucleus of any somatic cells. Ward and Coffey (1991) have proposed a model for the coiling of the DNA loop domain in sperm nuclei of rodent and human spermatozoa (Fig. 3).

In this model, the protamine-bound DNA is coiled, with a very slight bend in the protamine DNA complex, into concentric circles. These circles, of one loop, then collapse into a toroid-shaped structure, termed the DNA loop doughnut, in which the neutral DNA protamine complexes are tightly packed together by Van der Waal's forces. Each doughnut represents one DNA loop domain attached to the sperm nuclear matrix. The sperm nuclear matrix is not observed on standard sperm preparations and its observation required chromatin to be relieved of protamine compaction. In addition to the nuclear matrix, sperm nuclei contain a unique structure, termed the sperm nuclear annulus, located at the implantation fossa. When the nuclear matrix is disrupted during decondensation, the DNA remains anchored to this structure. Although the sperm nucleus is a highly ordered and well conserved structure from one sperm cell to another as well as from one individual to another, the organization of the mature sperm nucleus appears to be species-specific, limiting the ability to translate findings from mouse or bovine to human. Despite the near complete packaging of the sperm genome as protamine-associated DNA, it is increasingly clear that specific regions retain a somatic-like structure: 10%–15% histones are retained in spermatozoa in humans, but only ~1% in mice. Several studies have indicated a specific arrangement of the mammalian sperm chromosomes which could be involved in the formation of the male pronucleus and the first steps of the embryonic development.

The nucleus is surrounded by an unusual nuclear membrane closely applied to the nucleus: unlike somatic cells where numerous pores are scattered over most of the nuclear envelope surface, pores are absent in the nuclear sperm membrane except in the most

Fig. 2 Morphology and subcellular components of a normal human acrosome. (A) Schematic drawing. (B) Corresponding longitudinal and sagittal section observed by TEM. (C) Frontal view by SEM.

Fig. 3 Human sperm nucleus: structure and DNA organization. (A) DNA packaging in somatic versus sperm nuclei. (B) Diagram of the organization of the DNA in the nucleus of the human spermatozoa after extraction of the protamines by SDS and 2 M NaCl. The nuclear matrix retains the initial form of the nucleus and the DNA deploys outwards in the form of loops attached by their base to the matrix. Adapted from Ward, W.S. and Coffey, D.S. (1991). DNA packaging and organization in mammalian spermatozoa: Comparison with somatic cells. *Biology of Reproduction* **44**, 569–574.

posterior region of the head where the nuclear envelope has many folds/projections around the neck (redundant nuclear envelope), filling the posterior nuclear space. The nuclear membrane and the plasma membrane coalesce to form the posterior ring. The outer surface of the nuclear membrane thickens to constitute the basal plate at the implantation fossa of the tail.

Neck

The neck or connecting piece is a short segment between the sperm head and tail with a basic structural organization in all mammalian species despite species-specific fine variations. It has the shape of a truncated cone whose large base is a curved, electron-dense, leaflet called the capitulum facing the basal plate, a thickened, electron-dense zone of the nuclear membrane situated on the cephalic side and, the small base in the distal position in close juxtaposition with the initial part of the flagellum. At a high TEM magnification, many filaments arranged perpendicularly traverse this zone suggesting their role in the attachment of the flagellum to the head. The neck region comprises a proximal centriole, having a distinctive structure composed of nine microtubule triplets, surrounded by pericentriolar material, which lies in the implantation fossa and is oriented obliquely to the axis of the flagellum, in the dorso-ventral plane of the spermatozoon and, a modified distal centriole extending to the proximal part of the axoneme. It is flanked by nine segmented/cross-striated columns losing their individuality in their proximal portion where they fuse with the capitulum and developing distally where they dispose themselves in the continuation of the dense fibers at the level of the modified distal centriole. The distal centriole forms the axoneme, whereas the proximal centriole is associated with the formation of capitulum. Thus, the connecting piece originates from both the proximal centriole and the distal centriole. The sperm centriole is a key structure because, after fertilization, the egg polarity resets through the formation of the centrosome from the proximal centriole associated with the sperm head. The centrosome assembles the first mitotic spindle of the zygote.

The Flagellum or Tail

The tail is the longest part of the sperm cell, consisting of midpiece, principal piece, and end piece. The tail surrounded by a plasma membrane contains (Fig. 4):

- a centrally placed axoneme, composed of nine microtubule doublets surrounding a central doublet, (9 + 2 structure) resembling a cilium in structure which extends from the neck region to the end piece of the tail, surrounded by outer dense fibers (ODFs),
- a tight helix of wrapped mitochondria around the dense fibers which provide the energy (ATP) for cellular function and movement, extending from the neck to the principal piece, in the proximal part of the tail (the middle piece or midpiece),
- a fibrous sheath (FS) surrounding the dense fibers in the principal piece,
- an end piece where the axonemal 9 + 2 structure is lost, the nine doublets forming 18 single microtubules, the central tubule pair often lacks there and, ODFs and FS are absent.

Fig. 4 Neck and tail morphology and corresponding subcellular structures for a normal human spermatozoon. (A) Drawing of the aspect of the neck and half part of the tail in a longitudinal section observed by TEM. (B) Details of the structures of the neck region or connecting piece. (C) Drawing of a transversal section of the midpiece as observed by TEM. (D) Drawing of a transversal section of the principal piece as observed by TEM. (E) Schematic organization and components of the axoneme.

The periaxonemal structures, ODF and FS, are two unique cytoskeletal elements along the central axoneme which distinguish the sperm tail from simple flagella or cilia. Furthermore, ODF is a characteristic structure of the species with internal fertilization.

Axoneme

The mammalian axoneme (Fig. 4) present in all parts of the flagellum shares its basic structure with axoneme of most cilia and flagella in plants and animals. A central pair of microtubules is encircled by 9 microtubules doublets (configuration 9 + 2). Each doublet consists of one complete microtubules exhibiting 13 protofilaments (subunit A) and one incomplete, C-shaped, microtubule apposed to the wall of the complete microtubule (subunit B). The two subunits of the doublet are composed of tubulin protofilaments. From each subunit A, two dynein arms extend in the direction of the subunit B of the neighboring doublet. Dynein is a structural protein and an ATPase using ATP as a source of energy to generate flagellum movement. Each pair of peripheral microtubules is connected to the adjacent pair by nexine links, and connected to the central pair by nine radial spokes.

The flagellar movement results from the sliding of the microtubules by successive cycles of attachment and detachment of the internal and external dynein arms onto the adjacent microtubules. The radial spokes could intervene in the curvature of the flagellum.

Mitochondrial Sheath and Annulus

The midpiece contains the axoneme surrounded by the mitochondria wrapped helically, generally, end to end, around the outer dense fibers. The nature and organization of the helices including the number of mitochondria, the number of coils and finally, the overall length of the midpiece are species specific. The mitochondria deliver the ATP necessary for the autonomous displacement of the sperm cells.

At the caudal end of the mitochondrial sheath, the annulus or Jensen's ring, marks the limit between the midpiece and principal piece. At low magnification, the annulus appears as a dense homogeneous structure, it appears to consist of closely packed circumferentially oriented filamentous subunits. The flagellar membrane is firmly adherent to the annulus. The annulus is supposed to have the mechanical role of preventing a caudal displacement of the mitochondria during tail movement.

Outer Dense Fibers (ODFs)

ODFs are nine thin cylindrical cross-striated structures surrounding the peripheral doublets and associated with them (see the central caption in Figs. 1 and 4). ODFs extend from their junction with the striated columns to different parts of the principal piece.

They have a petal-like shape, a dense, inhomogeneous structure and a grossly rounded outline on transverse sections, while with variations in shape among them. In some species, satellite fibrils are visible between the outer fibers and doublets. They are unequal in size and length (in both humans and rats, ODFs extend to about 60% of the total length of the principal piece). All ODFs are thickest in the proximal part of the middle piece and progressively diminish in diameter from base to tip of tail. In humans, several ODFs have a larger section than others and these ODFs are the longest. ODFs are not thought to play an active role in axonemal or flagellar movement. Rather, cross-linked by extensive disulfide bridges, these fibers may serve to stiffen the tail and/or provide elastic properties.

Fibrous Sheath

The fibrous sheath develops on the entire length of the principal piece and lies subjacent (but not attached) to the plasma membrane. This structure could be unique to mammalian species and some birds. It is organized into two longitudinal columns connected by circumferentially oriented half circle ribs. These ribs thicken at their crossover to the columns and form broad bands in some species by interconnecting with each other. At high magnification, the columns are less closely packed than the subunits of the ribs. The ribs of the fibrous sheaths are separate elements except at their ends, occasionally they even bifurcate in tangential section. FS abruptly ends at the junction of the principal piece and end piece of the tail. FS is partly responsible for the specific wave movement of the sperm tail. Besides its role in sperm motion, the fibrous sheath works as a scaffold for proteins in signaling pathways, so it might be involved in regulation of sperm maturation, motility, capacitation, hyperactivation and/or AR.

Introduction

Interactions between cells are required for the maintenance or alterations/changes of cellular function, differentiation and growth, being therefore crucial for the normal physiology of tissues and organs. A great array of cellular interactions are required for the coordination of reproductive processes, at the structural and molecular levels. As millions or even billions of spermatozoa are daily produced in the testis, in a very active and complex process named spermatogenesis that occurs in the seminiferous epithelium, this naturally requires a very coordinated and organized interactions among testicular cells. For instance, since seminiferous cords/tubules formation, extensive interactions between the germ and Sertoli cells are needed for the development/self-renew and differentiation of germ cells, particularly in relation to the structural and nutritional aspects. In addition, the formation of the blood-testis or Sertoli cell barrier (SCB) between adjacent Sertoli cells, which creates a specialized microenvironment, is crucial for the development of more mature germ cells. In order to provide an optimal androgen milieu, in the intertubular compartment there is also a set of complex interactions and communications between the steroidogenic Leydig cells and other important interstitial cells. In this article, the main structural cellular interactions present in the testis (summarized in [Table 1](#)) is discussed, focusing particularly on its composition and importance for spermatogenesis.

Tubular Compartment

Sertoli–Sertoli Cell

During spermatogenesis, especially when germ cells are undergoing meiosis they show a different profile of surface antigens that are usually detected by the immune system and lead to an autoimmune reaction. In order to protect the development of these germ cells, Sertoli cells form the Sertoli cell barrier (SCB) (the most important component of the so-called blood-testis barrier), which helps to create an immune privileged environment inside the seminiferous epithelium, where foreign or autoimmunogenic antigens can be tolerated without inducing a detrimental immune response, leading ultimately to male infertility ([França et al., 2012](#)).

Initial evidence for the existence of the SCB came from different sources. Firstly, it was observed that the composition of the fluid present in the lumen of the seminiferous tubule is different from blood plasma or lymph. This difference would not exist if the tubule walls were permeable to molecules from the intertubular and basal compartments. Other evidence came from the use of tracers and dyes, determining the entry rate of different fluids and the relationship of a SCB to the fluid composition and solubility. Therefore, it was concluded that there must be a mechanism for controlling the entry of substances into the seminiferous tubule.

Table 1 Summary of the main junctions present in the testis and the cell types involved

<i>Junction</i>	<i>Cells involved</i>
Tight junctions	Sertoli–Sertoli cell (SCB ^a)
Adherens junctions	Sertoli cell-spermatogonia
	Leydig–Leydig cell
Gap junctions	Sertoli–Sertoli cell (SCB)
	Sertoli–germ cells
	Leydig–Leydig cell
Desmosomes	Sertoli–Sertoli cell (SCB)
	Sertoli cell-spermatocytes/early spermatids
Hemidesmosomes	Sertoli cell-basement membrane
Tubulobulbar complex	Sertoli–Sertoli cell (SCB)
	Sertoli cell-elongated spermatid (around spermiation)
Ectoplasmic specialization (ES)	Sertoli–Sertoli cell (SCB; basal ES)
	Sertoli cell-elongated spermatid (apical ES)
Intercellular bridge	Germ–germ cell
	Leydig–Leydig cell (Fetal)
Digitations	Leydig cell-macrophage

^aSCB, Sertoli cell barrier.

The SCB is formed by specialized junctional complexes between adjacent Sertoli cells, near the basement membrane, dividing the seminiferous epithelium into two compartments: basal and adluminal. Spermatogonia and early primary spermatocytes (preleptotene/leptotene stage) are located in the basal compartment. Spermatocytes must move from basal to the adluminal compartment, through a transient, intermediate compartment, without damaging the barrier structure. This intermediate compartment is created by a newly formed barrier, basal to the migrating cell, separating it from the basal compartment. The old junctional complex, luminal to the spermatocyte, is then dismantled and these cells enter the adluminal compartment. In this way, more advanced spermatocytes (from leptotene/zygotene onward) and the round and elongated spermatids are located in the protected adluminal compartment (Cheng and Mruk, 2012).

The main junctional constituent of the SCB is the tight junction, but desmosomes, gap junctions, tubulobulbar complexes and basal ectoplasmic specialization (the last two are testis-specific types of adherens junctions and will be discussed in more detail in the next section) are also present and collectively maintain this morphological immune barrier of the testis. The proteins involved include occludins, claudins, cadherins, catenins, and connexins, usually anchored by actin or vimentin filaments. This particular arrangement gives strength to the SCB, making it one of the tightest barriers in mammalian tissues.

Beyond strength and immunological protection, the barrier also provides for communication between the adjacent Sertoli cells, which is essential for coordination and signaling during the different stages of the seminiferous epithelial cycle. In addition, the junctional complexes restrict and control the transit of molecules from blood and interstitial spaces to the seminiferous tubule (and vice-versa), effectively limiting the immune system's access to the adluminal compartment of the seminiferous epithelium. The specialized microenvironment created is enhanced by immunomodulatory factors produced locally that cause an immunosuppressive response, instead of a possible destructive proinflammatory reaction. Sertoli cell polarity is also conferred by the presence of the barrier, illustrated by the usual basal location of the nucleus and an uneven distribution of cytoplasmic organelles within the Sertoli cell. This asymmetric organization is very important for the support of spermatogenesis, as physiological and cellular events take place in the corresponding cellular compartments in a stage-specific manner (Fig. 1).

In mammals, the establishment of the SCB occurs when the Sertoli cells stop proliferating and terminally differentiate, coinciding with the production of primary spermatocytes, tubular fluid secretion and lumen formation. As observed in the SCARKO mice model (mice with a selective ablation of the androgen receptor in Sertoli cells), germ cells are also important for the establishment and effectiveness of the barrier, as the meiotic phase of spermatogenesis can only be initiated in the presence of a competent SCB. Permeability and structure of the barrier is highly dynamic. As spermatogenesis proceeds, different molecules are transported to and from the interior of the tubule, depending on the spermatogenic cycle phase and the needs of the developing germ cells. Due to the presence of the barrier, hormones, such as FSH and LH for example, may act indirectly in germ cells, via Sertoli cells, which allows for a higher level of control by these supporting somatic cells over the spermatogenic process (França et al., 2016).

Sertoli–Germ Cell

The interactions between the Sertoli and germ cells in the seminiferous epithelium must be tightly regulated, because Sertoli cells provide the main control over spermatogenesis, providing nutritional and structural support for all developing germ cells. This Sertoli/germ cell interaction occurs through different types of junctions, such as adherens junctions, desmosomes, and gap junctions, depending on the stage of the seminiferous epithelium cycle and germ cell-specific requirements. For example, adherens junctions are usually detected between Sertoli and spermatogonia located in the stem cell niche, being important for stem cell homing and colonization. Desmosomes, in turn, are the major anchoring junction between spermatocytes/early spermatids and the Sertoli cells. Additionally, gap junctions provide crucial communications between adjacent germ cells, which is essential for the coordination of germ cell development throughout the different stages of differentiation (Fig. 2).

The testis forms a unique type of adherens junction, called ectoplasmic specialization (ES), which is not found in any other epithelium and is usually considered as one of the strongest anchoring junctions in the mammalian body (Cheng and Mruk, 2015). Despite participating in the SCB (basal ES), apical ectoplasmic specialization is also found at the Sertoli cell–elongated spermatid interface, conferring spermatid adhesion and polarity. Spermatid polarity involves the elongating heads pointing perpendicularly toward the basement membrane of the seminiferous tubule, allowing for maximum packing of developing spermatids in the seminiferous epithelium. This polarity and the very well-coordinated spermatogenic process allows the usually very high sperm output observed during spermatogenesis. Loss of spermatid adhesion and early release of the spermatids to the lumen of the seminiferous tubule is often caused by the disruption of cell polarity. In this context, it has also been shown that DICER (involved in the miRNA biosynthesis pathway) is an important player in the regulation of these Sertoli/germ cell junctions (Korhonen et al., 2015).

Structurally, the ectoplasmic specializations consist on bundles of actin microfilaments sandwiched between flattened cisternae of the Sertoli cell endoplasmic reticulum, and are present in the Sertoli cell membrane that faces the spermatid. This structure is closely associated with the microtubule network of the Sertoli cell, and is probably responsible for the movement of elongating spermatids across the seminiferous epithelium during the stages of the cycle. Injection of a microtubule stabilizer (taxol) lead to the retention of spermatids deep within the Sertoli cell crypts, while disruption of both ES and microtubules trapped the spermatids inside the epithelium, blocking their release at spermiation, until they were phagocytosed by the Sertoli cells. The molecular composition of the ES is constituted by nectin-, cadherin- and integrin-based protein complexes. A polarity protein complex, composed of

partitioning-defective3/partitioning-defective6/atypical protein kinase C (Par3/Par6/aPKC), is also an integrated component of the apical ectoplasmic specialization.

The apical ectoplasmic specialization appears in step 8 spermatids, replacing gap junctions and desmosomes as the only anchoring device between the spermatid and the Sertoli cell. Around the time of spermiation (steps 18–19 of spermiogenesis in rats, and steps 15–16 in mice), the apical ES undergoes degeneration, through the formation of structures similar to endocytic vesicles, which initiates the elimination of cytoplasmic debris resulting from the release of the spermatids. These vesicular structures are called tubulobulbar complexes. They form narrow tubular projections of the plasma membrane of the elongating spermatid head, penetrating an invagination of the Sertoli cell plasma membrane and forming a bulbous end. The tubular portion of the complex is surrounded by actin filaments, while the bulb is more associated with cisternae of the endoplasmic reticulum. The tubulobulbar complex facilitates the internalization of the disassembled apical ES junctions, in preparation for the release of sperm cells during spermiation (Vogl et al., 2013). Steroids, especially androgens, may be involved with the regulation of tubulobulbar complex formation, as it occurs concomitant with the occurrence of androgen-dependent stages of the seminiferous epithelium cycle (Fig. 3).

Fig. 3 Ectoplasmic specialization (ES) and tubulobulbar complex in elongating spermatids. (A) Schematic representation of the ectoplasmic specialization (*left*) and the tubulobulbar complex (*right*) and the relationship between the elongating spermatids and the Sertoli cell. Sertoli Cell–Tunica Propria

The exterior wall of the seminiferous tubule—the tunica propria—is composed mainly by the peritubular myoid cells, separated from the Sertoli cells by a basement membrane. This cell layer is responsible for structural integrity and contraction of the seminiferous tubule and regulatory interactions between the interstitial and tubular compartments. The peritubular myoid cells are in constant interaction with the nearby Sertoli cells and participate actively in the SCB (Skinner, 1993) and establishment of the stem cell niche. Their interaction is mainly mediated by the extracellular matrix of the basement membrane present between them, produced cooperatively by both peritubular and Sertoli cells. The peritubular myoid cells are capable of influencing the Sertoli cell function and vice-versa, changing the cellular synthetic profile, proliferation, differentiation and hormone responsiveness. Some paracrine factors have been shown to be involved in this regulation, such as activin, PModS, and growth factors (TGF α , TGF β , IGF-1), for example, but no structural interaction is described directly between these cells. Therefore, although not in direct contact, the Sertoli and peritubular myoid cells have a close association that involves a number of cell–cell interactions, mainly paracrine, in order to maintain Sertoli cell function, retention of peritubular myoid cell phenotype/activity, and spermatogenesis (Verhoeven et al., 2000).

Additionally, recent reports discuss the existence of a local apical ES-blood-testis barrier-basement membrane functional axis, mainly mediated by polarity proteins that could coordinate the events of junction restructuring in the seminiferous epithelium during spermatogenesis. This can be illustrated by proteins at the Sertoli cell–extracellular matrix interface, such as integrins, which can provide a feedback regulatory mechanism to modulate barrier integrity. In addition, proteins released during spermiation (e.g., fragments of laminins from the apical ES) can collaborate with polarity proteins to regulate SCB remodeling, directly or indirectly, via hemidesmosomes in the basement membrane. Experimental manipulation of hemidesmosomes integrins can disrupt the barrier function. These findings are supported by the fact that three cellular events that involve cellular interactions but at opposite ends of the Sertoli cell epithelium, namely (1) spermiation; (2) transit of primary spermatocytes and SCB restructuring; and (3) germ cell-cycle progression through meiosis that occurs concomitant in time. Therefore, it seems logical to assume that a regulatory loop would coordinate these cellular events (Wong and Cheng, 2009).

Germ–Germ Cell

During spermatogenesis, the germ cells go through successive cell divisions but cytokinesis is usually incomplete, resulting in daughter cells that are connected by cytoplasmic bridges. This process forms a syncytium of clonal cells derived from one spermatogonial stem cell. These bridges are maintained throughout spermatogenesis, even when germ cells migrate from the basal to the adluminal compartment through the SCB, and are eliminated only at the final stage of spermatid development, along with the residual cytoplasmic bodies. The presence of this syncytium is responsible for the synchronous development of germ cells by sharing essential signals, proteins, mRNA and organelles, which helps to coordinate mitosis, meiosis, differentiation and apoptosis of these cells (Smith and Braun, 2012).

The intercellular bridges are large and stable cytoplasmic channels, with an electron dense wall composed mainly of actin. Some proteins were shown to participate in these intercellular bridges, with Tex14 (Testis-Expressed Gene 14) being the most studied. This protein forms the mitotic spindle matrix and its absence in mice leads to spermatogenesis interruption at the meiotic phase and no formation of intercellular bridges. Tex14 blocks the complex centralspindlin that is formed by the proteins MKLP1 (Mitotic Kinesin-Like Protein 1) and MgcRacGAP (Male Germ Cell Rac GTPase-activating protein). This complex recruits abscission effector proteins, such as Cep55 (Centrosomal Protein 55-KDa), that are responsible for the completion of cytokinesis (Greenbaum et al., 2011).

In summary, the presence of cytoplasmic bridges between germ cells is a unique mode of intercellular communication, essential for fertility. However, the specific roles of the intercellular bridges for stem cell self-renewal, proliferation and differentiation of more advanced germ cells still need to be elucidated. The study of the germ cell's ability to inactivate abscission during cytokinesis could provide relevant information leading to the ability to regulate this cell division event in abnormal cells found in cancers (Fig. 4).

Intertubular Compartment

Leydig cells are the main component of the intertubular (interstitial) compartment of the testis. Among other important functions, these steroidogenic cells are responsible for synthesizing and secreting androgens, which are essential hormones for spermatogenesis and development of male sex characteristics. Other important components of the interstitial compartment include macrophages, fibroblasts, lymphocytes, mast cells, blood, and lymphatic vessels. The interaction between these components and the Leydig cells is very important for their development and differentiation and for the correct function of the testis. In this context, the most important and studied cell to cell structural interaction is between Leydig cells and macrophages, while less is known about the interactions with the other interstitial cells. It is worth mentioning that, although anatomically separated, Sertoli and Leydig cells highly modulate each other's development and function through paracrine interactions and secreted factors, such as androgens, inhibin, interleukin-1, growth factors, and estrogen.

Fig. 4 Intercellular bridges between germ cells. Leydig–Leydig Cell

Each Leydig cell is coupled to another Leydig cell through adherens and gap junctions and these connections are present in both fetal and adult populations. The presence of these junctions allows the exchange of ions and small molecules, besides controlling androgen secretion. Various proteins are involved in this communication, such as connexins (especially connexin-43, which abundance is dependent on LH levels) and cadherins, cell adhesion molecules (You et al., 2000; Poutis et al., 2010). Intercellular bridges with continuous cytoplasm can also be observed between some fetal Leydig cells (FLC).

In the adult population of Leydig cells (ALC), the gap junctions form before the increase in secretory activity of these cells, which is associated with puberty, when this population is established. The structural diversity and presence of these junctions increase along with the maturity of the adult Leydig cell and, in general, the ALC tend to form more gap junctions in comparison to the FLCs (Haider et al., 2007). Some of the gap junctions have a distinctive annular appearance, as they are formed between a cell process and the main cytoplasmic region of the other cell. However, the reason for this characteristic is still unknown. The presence of gap junctions between a group of Leydig cells strongly suggests a coordinated activity, which could be related to the variation in androgenic activity of Leydig cells depending on the stage of the spermatogenic cycle, as well as proximity of these Leydig cell groups to the tunica propria and the seminiferous tubule itself (Fig. 5).

Leydig-Immune Cells

In most species, Leydig cells are the most prevalent cell type in the testicular interstitium, while macrophages are the second most frequent cell. Testicular macrophages and Leydig cell numbers increase proportionately throughout development, as changes in their morphology are coordinated. This association suggests a functional relationship between both cells, but much remains to be learned. From studies mainly based on rats, it is estimated that there is approximately one macrophage for every three to five Leydig cells in the testis. The macrophages are usually in direct contact with adjacent Leydig cells through membrane associations or “digitations.” These interactions appear as long microvillus-like Leydig cell processes inserted within coated membrane invaginations into the macrophage cytoplasm. The digitations probably function as anchoring sites and for the exchange of signaling factors between both cells, as multiple coated vesicles are seen near these structures (Hutson, 2006). This interaction is

Fig. 5 Gap junctions between Leydig cells. (A, B) Electron microscopy images of the contact between two Leydig cells. The insert shows the gap junctions in higher magnification. (C, D) Immunohistochemistry for Connexin-43 in the mouse testis, between fetal Leydig cells (FLC; embryonic day 18.5) (C) and adult Leydig cells (ALC; 70 postnatal day) (D). Observe that the staining is also present between the Sertoli cells in the seminiferous cord/tubule. LC, Leydig cell; SC, Sertoli cell; BV, Blood vessel; Arrows, Gap junctions.

a remarkable characteristic of testicular macrophages, as there are no other examples of specialized areas of contact between macrophages and other cell types outside of the immune system. Another interesting aspect is that aging has a negative effect on steroidogenesis and one of the reasons could be the loss of these digitations between macrophages and Leydig cells, interrupting their communication and the exchange of molecules, including 25-hydroxycholesterol. This type of cholesterol is transferred from macrophages to Leydig cells under normal conditions and enter the steroidogenic pathway (Fig. 6).

Fig. 6 Relationship between Leydig cells and testicular macrophages. (A) Electron microscopy image of the Leydig cell contacting a macrophage in the adult mouse testis. (B) Schematic representation of the micrograph in (A), including the digitations (dotted rectangle), the structural interaction that exists between Leydig cells and macrophages. The macrophages are capable of influencing Leydig cell proliferation, differentiation, and testosterone secretion. It was shown that, after Leydig cell destruction by a cytotoxic drug (EDS; ethane 1,2-dimethane sulphonate), testicular macrophages were responsible for the phagocytosis of the apoptotic Leydig cells. There is a wave of proliferative activity when new Leydig cells repopulate the interstitium and a concomitant increase in the number of resident macrophages. In addition, the lack of macrophages during the proliferation wave disrupts Leydig cell recovery. A mouse model with reduced numbers of macrophages (osteopetrotic mouse; *op/op*) presents poor fertility, reduced testosterone levels and abnormal Leydig cells. Regarding testosterone production, the macrophages may have positive or negative effects, depending on the stimulus and the mediators produced. It has also been suggested that the testicular macrophages could metabolize Leydig cell secreted steroids, as peritoneal macrophages are able to convert androstenedione to testosterone and dihydrotestosterone (Hales, 2007).

It has also been suggested that Leydig cells could mediate the local regulation of the testicular leukocyte populations and thus provide an additional source of immunoregulatory polypeptides. Leydig cells have specific receptors and recognition molecules encoded on their surface and thus have the ability to interact with lymphocytes. As such, Leydig cell are the only highly differentiated endocrine cells that spontaneously form rosettes with lymphocytes, macrophages or eosinophils. This complex relationship is probably involved in the maintenance of the testis as an immunologically protected site, where immune cells appear to have restricted proinflammatory activity and immune responses are usually limited, possibly due to immunomodulatory factors secreted by Leydig cells. Androgens are also known to be immunosuppressive; therefore, it is also possible that immunological suppression is related to the high levels of intratesticular testosterone (Diemer et al., 2003).

Leydig-Endothelial Cells

Vascular and lymphatic endothelial cells are abundant in the well vascularized interstitial/intertubular compartment of the testis and their proximity to Leydig cells suggests their functional interaction. The diffusion of testosterone to blood circulation requires the communication between Leydig cells and the microvasculature, although the mechanism for this hormone transport is not completely known and may occur through passive diffusion. In this regard, cell contacts between Leydig and closely associated vascular endothelium have been described. A paracrine interdependence between Leydig and endothelial cells has been reported to possibly involve hormone transcytosis and vascular endothelial growth factors produced by the Leydig cells (Haider et al., 2007). Vascular endothelial cells produce the peptide endothelin, which was shown to stimulate testosterone production in the rat. It is also noted that the lymphatic endothelium associates with the peritubular wall and Leydig cell clusters. Endothelial cells of the testis are connected to each other by tight junctions and, in general, the capillaries are unfenestrated. These characteristics provide a supplemental mechanism of immunoprotection by controlling and protecting the testicular microenvironment, in addition to the SCB. However, further investigation is needed to clarify the cell interactions involved in this relationship (Martin, 2016).

Introduction

The testicular homeostasis relies on external stimuli, such as endocrine cues from the pituitary gland, as well as on a complex and permanent communication network between the different cell types within the testis. The latter is indeed necessary for the different cells to properly differentiate during early life. It is also responsible for the maintenance of all the different aspects of testicular functions in adulthood, notably androgen secretion by Leydig cells and continuous, daily production of spermatozoa within seminiferous tubules. To do so, Leydig cells, peritubular myoid cells, Sertoli cells, and germ cells at various stages of differentiation converse altogether by using several devices: locally-produced hormones, secreted paracrine factors such as growth factors, cytokines/chemokines or various organic compounds, as well as direct physical cell–cell interactions. According to a pioneer of the electronic microscopy, the anatomical complexity of the seminiferous epithelium is entirely unique (Fwacett, 1975). Therefore, studying cell–cell communications within the testis has always been very challenging.

The fundamental importance of this intercellular crosstalk has, for a part, been clearly illustrated by difficulties of germ cell cultures, especially the most differentiated ones (i.e., meiotic spermatocytes and postmeiotic spermatids), for which isolation from their micro- and macro-environments followed by culture alone inexorably leads to cell death. This absolute germ cell requirement for support from somatic cells, at both the physical and nutritional levels, also sustains the long-standing view that full spermatogenesis could not be achieved *in vitro* (for review, see Galdon et al., 2016). Besides, not only the germ cells require signals from somatic cells: the interactions between somatic cells are very numerous, and of many kinds, while germ cells also influence somatic cell functions (for review, see Jégou, 1993).

In addition to morphological/anatomical studies, dissecting cellular communication pathways has classically involved approaches where interactions were first disrupted, prior to eventual reconstruction. These include *in vitro* experiments in which primary testicular cells are isolated prior to culture (i) together with a second cell type; (ii) with the conditioned medium from a second cell type; or (iii) alone with a defined medium containing a potential paracrine factor or combination of factors to be tested. *In vivo* experiments have also been used to investigate cell communication within the testis, for instance through chemical treatments to perturb endocrine function or, even more drastically, by using chemical or physical treatments (irradiation, temperature) to completely ablate a specific cell type (for reviews, see Jégou, 1993; Smith et al., 2015). More recently, the democratization of high-throughput expression technologies (i.e., transcriptomics and proteomics) has allowed identifying promising candidate factors (for review, see Calvel et al., 2010) while functional genomics, especially in the mouse, has enabled the functional assessment of specific signaling pathways.

Altogether, these different and often complementary approaches have uncovered some crucial communication pathways within the testis, though many remain to be identified or require further investigations to be fully understood. In this article, rather than providing an exhaustive review of the literature, several exemplary signaling pathways will be used to illustrate the many cell relationships as well as the diversity of communication devices at play within the adult testis.

Paracrine and Autocrine Actions of Intratesticular Testosterone

Endocrine regulation is arguably the mechanism that has been the most intensively studied from the beginning of our attempts to understand testis physiology, that is, from the beginning of the 20th century. While some aspects of these regulatory pathways are beyond the scope of this article, it is worth mentioning that deciphering the local actions of testosterone has long consisted in trying to discriminate those from FSH action. Indeed, while *in vivo* manipulation of androgen levels has provided us with many insights into this crucial signaling pathway, feedback loops ultimately impact gonadotropin release (i.e., LH and FSH), making it almost impossible to ascertain the respective roles of testosterone and FSH. Furthermore, testosterone can be aromatized into estradiol, the latter being able to signal within the testis where estrogen receptors are also expressed. However, male mice lacking estrogen-receptor beta (ESR2) are fertile (Krege et al., 1998) while infertility in mice lacking estrogen-receptor alpha (ESR1) is indirect and results from impaired reabsorption of the luminal fluids in efferent ducts (Hess et al., 1997). Finally, mostly the use of *in vitro* models (e.g., primary testicular cell cultures) and the generation of mutant mice for the androgen receptor (AR) have finally helped us to precisely address this question.

Respective Role of Testicular Cells Mediating Testosterone Action

Testosterone classically mediates its effects through binding to AR, a nuclear receptor that will then modify the expression of specific target genes. Within the testis, Leydig cells, peritubular cells, Sertoli cells as well as vascular endothelial and smooth muscle cells represent potential mediators of the effects of testosterone as they all express AR. The first mutant mouse models for AR have thus proved to be somehow poorly adapted to precisely investigate testosterone signaling in the testis as their drastic phenotypes reflected the cumulative effects of AR ablation in all these somatic cell types. Still, they all pointed out towards an important

regulatory role of testosterone on meiosis completion and/or spermiogenesis, with spermatogenesis arrested at the pachytene spermatocyte stage in many cases. Cell type-specific ablation of the AR on the other hand has allowed a more precise dissection of testosterone effects on each of these cell types (for review, see [Chang et al., 2013](#)).

First, while the expression of AR in germ cells has been a matter of controversy, the absence of testicular phenotype in mutant mice with germ cell-specific AR ablation (GC-ARKO) demonstrated that the direct action of testosterone on germ cells was not essential for spermatogenesis ([Tsai et al., 2006](#)) and did not account for the germ cell defects observed in all other models. Similarly, the specific ablation of AR in vascular endothelial (VE) cells (VE-ARKO mice; [O'Hara and Smith, 2012](#)) or in vascular smooth muscle (VSM) cells (VSM-ARKO; [Welsh et al., 2010](#)) proved androgen signaling in these cells to be dispensable for spermatogenesis, even though testis weight of VSM-ARKO mice was reduced as a result of impaired vasomotion and subsequent Leydig cell function alterations.

Unfortunately, conclusions on how and to which extent AR signaling in Leydig cells directly influences spermatogenesis remain difficult to make. The Leydig cell-specific AR ablation (LC-ARKO mice) results in male infertility, with atrophied testes, spermatogenesis arrested at the round spermatid stage and a complete absence of epididymal sperm ([Xu et al., 2007](#)). In this model, however, mutant mice also exhibit primary hypogonadism, with low testosterone levels and high LH and FSH levels, which are likely to subsequently alter Sertoli and peritubular cell functions. Furthermore, the specificity of the Amhr2-Cre used for this knockout is dubious, as AR was not eliminated in all Leydig cells and, on the contrary, was lost in some Sertoli cells.

A similar issue of Cre recombinase specificity/characterization has prevented conclusions from a first peritubular cell-specific AR knockout model (PMC-ARKO; [Zhang et al., 2006](#)). Hopefully, a second, more robust model was subsequently generated (PTM-ARKO mice; [Welsh et al., 2009, 2012](#)). PTM-ARKO mice appeared normal at birth but became infertile during adulthood with a reduction in all types of germ cells and no sperm production. The progressive loss of spermatogonia, abnormal basement membrane, and altered secretion by Sertoli cells observed in these mice suggest that AR signaling in peritubular cells is essential for appropriate development and/or maintenance of the spermatogonial stem cell niche. Leydig cell functions were also found altered: testosterone circulating levels were normal but intratesticular testosterone and LH levels were increased, indicative of compensatory Leydig cell failure.

Finally, the investigation of Sertoli cell-specific AR knock-out mice (SC-ARKO) has provided important and consistent data ([Chang et al., 2004](#); [De Gendt et al., 2004](#); [Holdcraft and Braun, 2004](#)). Testes from mutants indeed display drastic weight reduction with spermatocytes blocked at the diplotene stage. While altered levels of testosterone and LH have sometimes been described, all models point toward defective maturation of Sertoli cells, disruption of the blood–testis barrier (BTB), compromised adhesion of round spermatids and spermiation failure as the primary causes for the observed germ cell defects. It can thus be concluded that AR signaling in Sertoli cells is essential for regulating seminiferous tubule remodeling in order to support meiosis completion and spermatid differentiation.

Identification of Androgen-Receptor Target Genes and Downstream Effective Pathways

While the AR signaling in Sertoli cells was found to be essential for spermatogenesis, the underlying mechanisms remain poorly understood. Many transcriptomic studies have been conducted in various models of testosterone depletion/restoration or in ARKO mice to identify testosterone-regulated genes in the testis (for review, see [Verhoeven et al., 2010](#)). The information provided by these experiments appeared somehow limited as no obvious genes important for spermatogenesis could be highlighted. Still, all these studies pointed out genes involved in cell–cell junction and adhesion, demonstrating further that testosterone mediates its effects by regulating the structure of seminiferous tubules and the BTB integrity.

In addition to the AR-mediated nuclear mechanism, two nonclassical pathways may also underlie the action of testosterone in the testis (for review, see [Rahman and Christian, 2007](#)). First, the binding of testosterone on a subset of AR induces their localization near the plasma membrane where they bind and activate Src tyrosine kinase. Src then phosphorylates EGFR, which triggers activation of the MAP kinase cascade, ultimately leading to the activation of the CREB transcription factor. In vitro experiments further demonstrated that the AR-dependent activation of Src and ERK signaling pathways regulates adhesion of germ cells to Sertoli cells, sperm release, as well as BTB dynamics. Second, through activation of an unidentified G-protein coupled receptor, testosterone induces Ca^{2+} influx in Sertoli cells, which is likely to alter many cellular processes. However, this pathway being AR-independent, it does account for the phenotypes observed in the different ARKO models.

Extrinsic Factors Regulating Spermatogonial Stem Cells

Our understanding of spermatogonial stem cell (SSC) biology has long been hampered because of (i) their low abundance within a highly complex tissue, (ii) the virtual absence of specific markers, and (iii) the lack of appropriate functional assay to assess and unequivocally identify these cells. The development of the SSC transplantation techniques in the mid-1990s ([Brinster and Avarbock, 1994](#); [Brinster and Zimmermann, 1994](#)) finally allowed to evaluate the stem cell activity of enriched cell populations and to correlate this activity with the expression of potential markers for subpopulations of undifferentiated spermatogonia. Together with the setting up of appropriate cell culture conditions, this powerful tool has allowed rapid improvement of our knowledge regarding the functional characteristics of SSC and how their microenvironment controls the balance between self-renewal and differentiation.

The GDNF Signaling Pathway

Our understanding of SSC biology has greatly progressed thanks to the identification of glial cell-line neurotrophic factor (GDNF), a distant member of the TGF β family, as a crucial regulator of SSC maintenance. *Gdnf*-null mice die shortly after birth, thus preventing from the evaluation the role of this factor during spermatogenesis. Heterozygous mice for *Gdnf*, on the other hand, are viable and fertile. They however display age-related spermatogenesis defects, with tubules often containing only Sertoli cells as a result of progressive SSC pool depletion. Consistently, the overexpression of *Gdnf* resulted in the exact opposite phenotype, that is, the accumulation of undifferentiated spermatogonia, clearly demonstrating the important role of GDNF in regulating SSC maintenance (Meng et al., 2000) (Fig. 1).

Since then, SSC cultures typically involve addition of GDNF in the medium, allowing to expand these cells for weeks/months while maintaining their stem cell activity. Such cultures have also been used to decipher the intracellular networks that mediate GDNF action in SSC: GDNF first binds to GFR α 1, a GPI-anchored transmembrane molecule, which in turn activates the RET tyrosine kinase, both proteins being present at the membrane of undifferentiated spermatogonia. Upon autophosphorylation, RET next activates several kinases of the Src family (e.g., Src, Yes, Lin, and Fin), the PI3/Akt signaling pathway as well as the Ras/ERK1/2 pathway. The activation of these intracellular pathways together with the subsequent transcription of downstream gene

Fig. 1 Molecular cell-cell interactions within the testis. A nonexhaustive view of molecular factors involved in cell-cell communication between testicular cell types is presented. Leydig cell stimulation by LH triggers testosterone (T) secretion which acts in an autocrine manner on Leydig cells or in a paracrine manner on Sertoli cells and peritubular cells. T signaling in Sertoli cells regulates the blood-testis barrier (BTB), meiosis completion by spermatocytes, spermatid differentiation as well as germ cells adhesion and spermiogenesis. In peritubular cells, T notably upregulates GDNF that controls spermatogonial stem cell maintenance. FSH on the other hand only signals through Sertoli cells leading to upregulation of GDNF, KITLG, and NRG1. Both KITLG and NRG1 subsequently promotes differentiation of spermatogonia. The entry of retinoic acid (RA) within the seminiferous tubules is prevented by CYP26A1-C1 activity in peritubular cells. Instead, RA is synthesized by spermatocytes and acts on spermatogonia by promoting their differentiation as well as by triggering their commitment to meiosis. The phagocytosis of residual bodies (i.e., remaining cytoplasm from elongated spermatids as they detach from Sertoli cells) by Sertoli cells induces IL1A secretion in these cells, and IL1A subsequently induces IL6 in an autocrine manner. IL1A finally stimulates spermatogonial cell proliferation while IL6 inhibits meiotic DNA synthesis. Protein factors are indicated within a rectangle while organic compounds (i.e., RA and T) are within an oval.

targets modify cell cycle progression of SSC. Importantly, an early microarray experiment aiming at identifying GDNF-regulated genes compared isolated SSC cultured with or without this factor (Oatley et al., 2006) and pointed out several transcription factors (Bcl6b, Etv5, Id4, Lhx1, Pou3f1, and T) which were all later on demonstrated to be important for SSC fate.

GDNF is expressed in Sertoli cells and peritubular cells. However, the paracrine regulation of SSC by GDNF is most of times attributed to Sertoli cells only. Since SSC lie on the basement membrane of seminiferous tubules, it can easily be imagined that GDNF from nearby peritubular cells may influence SSC as well. More, the specific ablation of *Gdnf* in peritubular cells actually results in complete absence of germ cells in the adulthood following progressive loss of SSC after the first spermatogenetic cycle. While it is tempting to speculate that GDNF from Sertoli cells is also important for SSC maintenance, a Sertoli cell-specific knockout for GDNF will be required to draw such conclusion. Besides, the potential interaction between Sertoli cells and peritubular cells through this signaling pathway will require further investigations since GDNF was also shown to increase Sertoli cell proliferation. Interestingly, *Gdnf* is upregulated by testosterone and FSH in peritubular cells and Sertoli cells, respectively (Chen et al., 2014; Tadokoro et al., 2002) (Fig. 1). Furthermore, activation of NOTCH in Sertoli cells by JAG1 from spermatogonial cells leads to *Gdnf* downregulation (Garcia et al., 2017). A complex interplay of endocrine and paracrine factors thus controls GDNF levels in order to regulate the delicate balance between self-renewal and differentiation of SSC.

Other Factors Controlling SSC Self-Renewal

The maintenance of SSC allowed by addition of GDNF in culture media has also enabled to demonstrate in vitro the roles for several other testicular factors in self-renewal and/or survival of SSC, most of which being dependent on, or acting downstream of GDNF itself. These include IGF1 (Huang et al., 2009) produced by Leydig cells, LIF (Dorval-Coiffec et al., 2005; Guan et al., 2006) produced by peritubular cells, FGF2 (Takashima et al., 2015), CXCL12 (Yang et al., 2013), CCL9 (Simon et al., 2010), and WNT5A (Yeh et al., 2011) produced by Sertoli cells, CSF1 (Oatley et al., 2009) produced by Leydig cells, macrophages, perivascular cells and/or peritubular cells, as well as a few factors that are produced by differentiated germ cells, such as VEGFA₁₆₄ (Caires et al., 2012), BMP8A (Zhao et al., 1998), and BMP8B (Zhao et al., 1996).

Factors Involved in Spermatogonial Differentiation

It is only over recent years that our knowledge on SSC self-renewal has rapidly progressed. On the other hand, one of the first identified factor regulating spermatogonial fate—Kit ligand (KITLG, also called KITL, steel factor or stem cell factor)—triggers their differentiation (for review, see Zhang et al., 2011b). In the adult testis, KITLG is expressed and secreted by Sertoli cells. Upon binding to KITLG, the KIT proto-oncogene receptor tyrosine kinase (KIT, C-Kit or CSFR) transiently activates PI3K/AKT and ERK1/2 signaling pathways, ultimately promoting G1/S transition and DNA synthesis in A1–A4 differentiating spermatogonia (Fig. 1). Indeed, KIT is present at the surface of differentiated spermatogonia, but not of SSC. The drastic reproductive phenotypes of several mutant mice at the *white spotting* (W) and *steel* (Sl) loci, which contain KIT and KITLG, respectively, clearly demonstrate the indispensable role of this signaling pathway. For instance, a single point mutation in the PI3K-binding site of KIT induces male fertility with complete arrest of spermatogenesis at the spermatogonial stage (Blume-Jensen et al., 2000). Additionally, a truncated form of KIT, tr-KIT, is specifically expressed in spermatids, suggesting that KIT signaling may also be involved during spermiogenesis and/or fertilization. Importantly, FSH, but not testosterone, upregulates KITLG in Sertoli cells, providing a first mean to control this pathway (Fig. 1). Fine-tuning regulation of KIT expression in spermatogonial cells is also necessary to ensure appropriate balance between self-renewal and differentiation (for review, see Rossi, 2013). Transcription factors SOHLH1/2 have been shown to directly activate the transcription of KIT in spermatogonia, while the transcriptional repressor PLZF switches it off as meiosis is initiated. Most importantly, retinoic acid (RA) was found to render spermatogonia responsive to KITLG by upregulating KIT at both the transcriptional and translational levels (Busada et al., 2015; Raverdeau et al., 2012). RA therefore appears a critical signaling pathway upstream of KITLG/KIT (see below, section **Extrinsic Factors Regulating Spermatogonial Stem Cells**).

Additional paracrine factors involved in spermatogonial differentiation have also recently been identified. The Sertoli cell-specific ablation of NRG1 demonstrated this member of the epidermal growth factor (EGF) to be crucial for type A spermatogonia differentiation as well as for transition from type B spermatogonia to preleptotene primary spermatocytes. Further in vitro experiments evidenced that, like KITLG, NRG1 is a downstream effector of RA-mediated spermatogonial differentiation and is upregulated by FSH in Sertoli cells. NRG1 however signals through the EGF receptor tyrosine kinase ERBB2 in spermatogonia, independently of the KITLG/KIT signaling pathway (Chapman et al., 2015; Zhang et al., 2011a). Additionally, BMP4 produced by germ cells at various developmental stages, was demonstrated to enhance spermatogonial differentiation in vitro by upregulating KIT in a RA-dependent manner (Pellegrini et al., 2003). Similarly, INHBA from Sertoli cells and germ cells was found to promote SSC differentiation in vitro (Nagano et al., 2003). Finally, while VEGFA₁₆₄ was proved to promote SSC self-renewal (see above), VEGFA_{165b} on the contrary induces their differentiation (Caires et al., 2012).

Retinoic Acid Pathway and Male Germ Cell Differentiation

One of the most important breakthrough in the field of reproductive biology has been the identification of retinoic acid (RA) as the substance triggering the germ cells to undergo meiosis. Strikingly, while it was known for almost a century that vitamin A, the precursor for the synthesis of RA, was essential for spermatogenesis (Wolbach and Howe, 1925), the fact that RA actually is

the active metabolite of this pathway was only recently discovered thanks to studies on fetal gonads: fetal male germ cells were indeed found to enter meiosis (which they normally do only after birth, from puberty onwards) in mice lacking the retinoid-degrading enzyme CYP26B1 (Bowles et al., 2006). In this mouse fetal gonad model, RA thus constitutes the ovarian “meiosis-inducing substance” and CYP26B1, which is specifically expressed in the fetal testis, corresponds to the “meiosis-preventing factor” (Byskov and Saxén, 1976). Subsequently ALDH1A1 was identified as the enzyme providing a source of RA in the mouse fetal ovary (Bowles et al., 2016).

The situation in the juvenile and adult testes, however, appears somewhat more complicated: RA does not only seem to drive meiosis onset through the upregulation of *Stra8*. More, its primary function appears to regulate spermatogonial differentiation by turning on KIT signaling (Fig. 1). Either vitamin-A-deficient models or animals lacking vitamin A metabolizing or signaling proteins have indeed demonstrated that removing RA prevents male germ cells from developing further than undifferentiating spermatogonia. Additionally, the RA signaling pathway in the adult testis requires an incredibly fine-tuned regulation at both the spatial and temporal levels so germ cells within the testis do not differentiate synchronously, and rather go through continuous spermatogenesis and sperm production. The initiation of spermatogonial differentiation, that is, the A to A1 transition, occurs precisely at stages VII–VIII of the mouse seminiferous epithelium cycle while the transition from type B spermatogonia to leptotene spermatocyte initiates slightly earlier, at stage VI. This timing and coordination of germ cell differentiation was recently proposed to result from oscillations or pulses of RA along the seminiferous epithelium, with peak levels at stage VII–VIII (Hogarth et al., 2013). More, this RA gradient, by promoting spermatogonial differentiation in a reoccurring manner, has been proposed to both initiate and maintain the cycle of the seminiferous epithelium (for review, see Griswold, 2016).

The fine-tuning of RA levels within the testis is achieved thanks to the cellular compartmentalization of enzymes and proteins involved in RA synthesis, degradation, uptake, and storage as well as by developmentally-regulated expression of these factors (Sugimoto et al., 2012; Vernet et al., 2006). Peritubular cells express all three RA-degrading enzymes (CYP26A1, B1, and C1), thus constituting a catabolic barrier that prevents RA, either circulating or synthesized by Leydig cells, to enter seminiferous tubules. The source of RA within the tubules therefore relies on the expression of ALDH1A1 and ALDH1A2, two of the three RA synthesizing enzymes, by Sertoli cells and spermatocytes, respectively (Fig. 1). The dogma for retinoid signaling in the testis was therefore that retinol was uptaken by Sertoli cells and transformed into RA, which would finally act on undifferentiated spermatogonia through RA receptors to trigger differentiation and subsequent commitment to meiosis. This simplistic view has however been challenged recently both in terms of RA origin and receptivity. First, testes from neonatal mutant mice with Sertoli cell-specific ablation of the three RA synthesizing enzymes (*Aldh1a1-3^{ser}-/-*) only contain spermatogonia blocked in an undifferentiated state, demonstrating that RA from Sertoli cells was indeed indispensable for spermatogonial differentiation during the first wave of spermatogenesis. Further culture experiments of these mutant testes however demonstrated that RA was used in an autocrine manner to activate RAR α in Sertoli cells. This suggests that the RA-induced spermatogonial differentiation in the juvenile testis is indirect and that a yet unidentified paracrine signal from Sertoli cells is involved in this process (Raverdeau et al., 2012). Second, when these same *Aldh1a1-3^{ser}-/-* mice were injected with a single RA dose, not only spermatogonia could differentiate up to preleptotene spermatocytes, but full spermatogenesis could even be observed several weeks after the injection. These results implies that the RA required for the A to A1 transitions after the first round of spermatogenesis is not provided by Sertoli cells, but rather by leptotene/pachytene spermatocytes thanks to ALDH1A2 activity. Furthermore, mutant mice lacking RAR γ in spermatogonia display normal progression of the first spermatogenetic cycle but exhibit an age-related progressive spermatogenetic decline as spermatogonia do not differentiate anymore (Gely-Pernot et al., 2012). This model therefore demonstrated that, unlike in the juvenile testis where RA-induced A to A1 transition involves paracrine signaling from Sertoli cells, the spermatogonial differentiation beyond the first wave of spermatogenesis involves the direct RA-signaling activation through RAR γ in undifferentiated spermatogonia (Fig. 1).

Influence of Germ Cells Upon Somatic Cells

Germ cell differentiation during spermatogenesis relies on both intrinsic factors specific to the germline and on extrinsic signals from surrounding somatic cells. While germ cells appears dispensable for testis differentiation during fetal life, germ cell products, such as the above-mentioned RA or BMP4, are likely to influence somatic cells in order to induce and/or maintain somatic cell functions after birth. Due to their intimate location within the seminiferous epithelium, Sertoli cells which surround and support germ cells all along their differentiation process represent a preferential target for such signals.

In agreement with this hypothesis, the appearance of new germ cell types during the first spermatogenetic wave coincides changes in Sertoli cell biology: they stop proliferating, establish cell–cell junctions in order to create the BTB and start secreting the seminiferous fluid (evidenced by the appearance of a lumen) while acquiring a mature molecular phenotype (e.g., loss of AMH and KRT18 the gain of AR and GATA1) (for review see, Sharpe et al., 2003). Conversely, the disappearance of specific germ cell types, either induced experimentally in animals or under pathological conditions in humans, results in abnormal Sertoli cell activity, suggesting again the potential involvement of differentiated germ cells in maintaining adult Sertoli cell functions. To address such mechanisms, a number of in vitro experiments were conducted where immature Sertoli cells were cultured together with enriched germ cell preparations or their-conditioned media. These experiments notably demonstrated that germ cell and/or their secreted products indeed influence the secretion of Sertoli cells (e.g., transferrin, ABP, inhibin B, and estradiol) and promote the formation of the BTB (Clifton et al., 2002; Le Magueresse and Jégou, 1986; Le Magueresse et al., 1988). Co-culture experiments and germ cell depleted models were also used to demonstrate gene expression regulation by germ cells, providing one of the means

by which cyclical gene expression in the Sertoli could be established and/or maintained (O'Shaughnessy et al., 2008; Syed et al., 1999).

In this context, one of the very few pathways investigated into details is the specific regulation of the interleukin 1 alpha (IL1A) by late spermatids. Residual bodies released from spermatozoa as they detach from the seminiferous epithelium are rapidly phagocytosed by Sertoli cells, which triggers the production and secretion of IL1A. Subsequently, IL1A induces the secretion of IL6 by Sertoli cells in an autocrine, lipoxygenase-dependant mechanism (Syed et al., 1995). Importantly, IL1A and IL6 were found in vitro to stimulate spermatogonial cell proliferation (Pöllänen et al., 1989) and to inhibit meiotic DNA synthesis (Hakovirta et al., 1995), respectively. Furthermore, IL1A was also shown to regulate the BTB remodeling (Lie et al., 2011). Taken together, these data suggest that residual bodies and their phagocytosis by Sertoli cells could constitute an important signal controlling both germ cell differentiation and the dynamics of the seminiferous epithelium (Jégou, 1991).

The regulation of somatic cells by germ cells has caught relatively little attention as compared to other cell–cell interactions within the testis. The extent to which germ cells indeed account in the overall regulation of testis homeostasis therefore remains relatively unclear. More, the molecular factors that mediate these effects, either secreted by or present at the membrane of germ cells, are also largely unknown.

Conclusions

As illustrated throughout this article, the extreme morphological entanglement of testicular cells is reflected by a systematic communication network between Sertoli cells and germ cells, somatic cells within each of the two main anatomical compartments of the testis, as well as between these compartments. The communication between testicular cells is absolutely crucial to ensure normal reproductive functions in the male. Describing in a systematic way our current knowledge of these complex and many cellular interactions would definitely exceed the length constraint of the present article. Therefore, many molecular pathways at play within the testis could not be detailed here. These include notably the prostaglandin pathway, the endocannabinoid system or the signaling by bile acids, the three of them emerging as important regulators of male fertility (for reviews, see du Plessis et al., 2015; Frungieri et al., 2015; Sèdes et al., 2017).

Some fundamental aspects of testis physiology that are highly relevant in terms of cell–cell interactions were also voluntarily omitted as they are reviewed elsewhere within this encyclopaedia. For instance, the BTB constitutes a crucial immunological barrier which continuous remodeling, to allow the transport of preleptotene spermatocytes, results from the combination of direct cell–cell interactions as well as of paracrine and endocrine regulations. Additionally, the immune privilege provided by the testicular environment, to ensure protection of differentiated germ cells from the host immune response, also relies on locally-produced factors, including androgens, cytokines and bioactive lipids.

While many paracrine pathways that regulate testis physiology are now being well-characterized, much work is still needed in order to clarify how they may account for the etiology of many cases of unsolved male infertility. Noteworthy is that a better understanding of these delicate regulatory networks is also likely to help identifying relevant targets for male contraceptives.

DEVELOPMENT

Formation of the Testis Primordium

Formation of the Testis From the Bipotential Gonad

The testes form from a primitive undifferentiated gonad or genital ridge that has the potential to become either testes or ovary. In this article, we will describe the earliest events in testis development, when gonadogenesis, or formation of the gonads, occurs. Because most of the experimental evidence comes from studies using the mouse as a model organism, the morphological and molecular events during gonad formation are discussed mostly with reference to mouse development.

A functional gonad requires the presence of germ cells and somatic cells in order to produce gametes and hormones. The somatic cells of the gonads originate from the coelomic epithelium, a thin layer of epithelial cells that covers the gonad. While the primitive gonad is establishing, germ cell precursors, or primordial germ cells, migrate into the gonad from elsewhere in the embryo (discussed in the second part of this article). Key steps in forming the gonad are (1) proliferation of the coelomic epithelial cells, (2) ingression of the coelomic epithelium into the gonad proper, and (3) subsequent expansion and sexual differentiation of the somatic cells (Fig. 1). This process is controlled by a group of transcription factors and signaling molecules. At the onset of gonadogenesis, the coelomic epithelial cells that are destined to form the gonad become positive for the transcription factor Wilms' tumor 1 (WT1) (Kreidberg et al., 1993). Without *Wt1*, thickening of the coelomic epithelium is reduced dramatically (Kreidberg et al., 1993). The coelomic epithelium proliferates in an anterior to posterior fashion. The anterior-posterior thickening of the coelomic epithelium and the subsequent establishment of the gonad require the action of another transcription factor GATA binding protein 4 (GATA4) (Hu et al., 2013). GATA4 expression in the anterior part of the gonad precedes the initial thickening of the coelomic epithelium, and without *Gata4*, proliferation of the coelomic epithelial cells, and subsequent formation of the gonad fail to occur (Hu et al., 2013). The thickening of the coelomic epithelium is followed by a breakdown of its underlying basement membrane and ingression of the coelomic epithelial cells to form the gonad proper. In addition to WT1 and GATA4, the coelomic epithelial cells also express steroidogenic factor 1 (SF1), an orphan nuclear receptor that is important for gonad formation (Hoivik et al., 2010). Without functional SF1, the gonad does not expand properly and the gonadal cells eventually die (Luo et al., 1994). The early SF1 expression in the coelomic epithelium is promoted by GATA4 and two homeodomain proteins SIX1 and SIX4 (sine oculis homeobox homologs 1 and 4) (Hoivik et al., 2010; Fujimoto et al., 2013).

After its initial thickening, the coelomic epithelium continues to proliferate and provides progenitors to the developing gonad. This proliferation of the coelomic epithelial cells is promoted by Lim homeobox 9 (LHX9) and insulin signaling. Loss of *Lhx9* or insulin receptor and IGF type I receptor (*Igf1r*) result in stunted gonad development due to decreased proliferation of gonadal somatic cells (Birk et al., 2000; Pitetti et al., 2013). What the coelomic epithelial cells become after proliferation is determined by the polarity of the cells. The coelomic epithelium proliferates asymmetrically, where the progenitor cells remain as a part of the coelomic epithelium and maintain an undifferentiated epithelial cell fate. The daughter cells, on the other hand, ingress to the gonad proper, and acquire mesenchymal characteristics. During the ingression process, epithelial cells lose their cell polarity and cell-cell connections, and migrate through the basement membrane. Once they pass through the basement membrane, the ingressing epithelial cells form clusters that become the future somatic cells in the testis (Fig. 1). Multiple factors and pathways are involved in the invagination of the coelomic epithelium. Homeodomain transcription factor EMX2 and possibly SIX1/SIX4 are critical for the proliferation and the subsequent migration of the coelomic epithelial cells through the basement membrane. Without *Emx2*, the coelomic epithelial cells accumulate on the gonadal surface and fail to migrate and differentiate (Kusaka et al., 2010). A tight regulation of Notch signaling pathway is also necessary to maintain the asymmetric divisions and proper balance between progenitor and differentiated cell populations. A defect in the Notch signaling pathway results in abnormal accumulation of the progenitors and a failure of them to differentiate into the somatic cells in the testis (Potter et al., 2016; Lin et al., 2017). The coelomic epithelial cells that enter the gonad during sex determination become Sertoli cells. Proliferation and ingression of coelomic epithelial cells continue after sex determination, but cells ingressing at this time contribute to fetal and adult Leydig cell populations in the interstitium (Karl and Capel, 1998).

After the gonad has formed, it is important to ensure that new somatic cell progenitor cells survive and proliferate to form the testes. The survival of gonadal cells is controlled by SF1 and WT1. In the absence *Sf1* and *Wt1*, the coelomic epithelium begins to thicken during the earliest steps of gonad development, but then these structures gradually disappear through apoptosis of the gonadal somatic cells (Luo et al., 1994; Kreidberg et al., 1993). In addition to survival, sufficient proliferation of gonadal somatic cells is necessary for testis development (Schmahl and Capel, 2003). Without proliferation of the somatic cells in this early phase, such as in knockout mouse models for *Pbx1* and *Cbx2*, the resulting gonads are very small and poorly formed (Schnabel et al., 2003; Katoh-Fukui et al., 1998).

Fig. 1 Formation of the gonad. (A) The coelomic epithelium (CE), which lies on top of the future gonad, has an intact basement membrane prior to gonad formation. (B) Coelomic epithelial cells begin to express GATA4, prior to proliferation and thickening of the coelomic epithelium. (C) The cells that are destined to become gonadal somatic cells begin to express SF1. The basement membrane disintegrates and cells begin to ingress into the gonad. (D) Supporting cell progenitors (pre-Sertoli cells) continue to enter the gonad and proliferate. Primordial germ cells arrive to the gonad and they are surrounded by the pre-Sertoli cells. (E) The proliferating precursor cells from the coelomic epithelium contribute also to interstitial cells. Modified from Piprek, R. P., Kloc, M., and Kubiak, J. Z. 2016. Early development of the gonads: Origin and differentiation of the somatic cells of the genital ridges. *Results and Problems in Cell Differentiation* **58**, 1–22.

Development of the genital ridges lays the foundation for testicular development by ensuring that sufficient numbers of Sertoli cell precursors are established. Once the testis primordium is established, testicular development continues with migration of interstitial cell progenitors, vascular cells and macrophages into the gonad, which is covered in detail in other articles.

Primordial Germ Cell Formation and Migration

While the gonad is forming, primordial germ cells that migrate from the hindgut begin to enter the gonad. Primordial germ cells first gain their identity as a few cells in the epiblast, an embryonic structure next to the embryonic ectoderm (Fig. 2A). Primordial germ

Fig. 2 Specification and migration of primordial germ cells. (A) Primordial germ cells are first specified in the epiblast. This process is controlled by BMP from the extraembryonic ectoderm and WNT3 signaling from the visceral endoderm. (B) As the embryo develops the primordial germ cells migrate to the base of the allantois. (C) When primordial germ cells begin their long migration toward the gonads, they leave the allantois and enter the hindgut. They migrate through the hindgut and mesentery until they reach the gonads. Arrows denote direction of migration. Modified from Tang, W. W., Kobayashi, T., Irie, N., Dietmann, S., and Surani, M. A. 2016. Specification and epigenetic programming of the human germ line. *Nature Reviews. Genetics* **17**, 585–600; Rosen, M. P., and Cedars, M. I. 2011. Female reproductive endocrinology and infertility, In D. G. Gardner and D. Shoback (eds.), *Greenspan's basic & Clinical endocrinology*, 9th edn. (New York, NY: The McGraw-Hill Companies). Chapter 13.

cell specification is directed by cues from the adjacent structures: bone morphogenetic protein (BMP) signaling from the extraembryonic ectoderm and Wnt family member 3 (WNT3) from the visceral endoderm (Tang et al., 2016). These signals are sensed by the presumptive primordial germ cell progenitors, and activate genes that distinguish them from somatic cells.

As the embryo develops, primordial germ cells relocate to the extraembryonic region at the base of the allantois, a membrane that is important for the development of the umbilical cord and placenta. From the allantois, primordial germ cells migrate through the hindgut and mesentery toward the gonads (Fig. 2B). Several factors promote primordial germ cell survival during the long migration process, such as DND microRNA-mediated repression inhibitor 1 (DND1), and Kit ligand (KitL) and stromal cell derived factor 1 (SDF1, also known as CXCL12) (Youngren et al., 2005; Gu et al., 2009; Molyneaux et al., 2003).

There are two theories on the migration process of the primordial germ cells: active migration of the primordial germ cells toward the gonads, which is induced by signals secreted by cells along the migratory path, or passive movement of primordial germ cells due to physical changes of the embryonic structure (Harikae et al., 2013). According to the theory of active migration, primordial germ cells sense chemoattractant signals secreted by somatic cells in the gonad, adjacent mesonephros, and mesentery. In response to these signals with the specific receptors, primordial germ cells actively migrate through the hindgut toward the gonads. Examples of chemoattractant signalling pathways are Kit ligand and c-Kit receptor (also known as Steel and KIT, respectively), and SDF1 and its receptor CXCR4 (chemokine (CXC motif) receptor 4). Kit pathway is involved in primordial germ cell proliferation, survival, and migration throughout the migration period (Gu et al., 2009). Without Kit ligand or its receptor, mice have reduced proliferation of migrating primordial germ cells during fetal life and are sterile as adults. Kit ligands elicit their action within a short range, meaning that the target cell has to be close to the cell secreting the Kit ligand. Interestingly, cells that produce Kit ligand form a path which migrating primordial germ cells follow. Kit ligand-expressing cells surround primordial germ cells that are already in the allantois right after primordial germ cells have become specified (Gu et al., 2009). As migration begins, Kit ligand is expressed both in the gonads and the midline area through which primordial germ cells migrate. Later on, when primordial germ cells reach the gonads, Kit ligand expression is switched off in the migratory path outside the gonads, but maintained in the gonads. Kit ligand not only promotes primordial germ cell survival and proliferation, but also influences their motility. Without Kit ligand, primordial germ cells migrate to the correct direction but at a lower rate than normal, resulting in fewer primordial germ cells reaching the gonads (Gu et al., 2009).

There are several similarities between the roles of Kit/Kit ligand and the SDF1/CXCR signaling pathways in controlling primordial germ cell migration. If SDF1 or its receptor CXCR4 are deleted in mice, very few germ cells reach the gonads and the adult mice are sterile (Ara et al., 2003; Molyneaux et al., 2003). SDF1 also promotes primordial germ cell survival and is expressed in the somatic cells along the migratory path of primordial germ cells in a similar fashion as Kit ligand. However, unlike Kit ligand, SDF1 is involved in establishing the direction of primordial germ cell migration. If ectopic SDF1 is present in embryonic organs other than the gonads, primordial germ cells begin to migrate toward that region erroneously (Molyneaux et al., 2003). Also, in

contrast to Kit ligand which is necessary for primordial germ cell migration from start to finish, SDF1 is dispensable for the early stages of migration, but required for the later stages of migration through the mesentery and hindgut to the gonads (Molyneaux et al., 2003; Ara et al., 2003). In conclusion, KIT and SDF1/CXCR4 signaling pathways play complementary roles in primordial germ cell proliferation, survival, and migration.

The second theory for primordial germ cell migration is the passive theory: when primordial germ cells are first incorporated into the hindgut endoderm, proliferation, and expansion of the hindgut passively propels primordial germ cells forward and toward the gonad (Harikae et al., 2013). If the hindgut does not expand, primordial germ cells are stuck at the hindgut entrance. It has been proposed that both of the active and passive theories are involved: the initial long-range migration of the primordial germ cells is promoted by passive translocation, but the survival and final steps of migration before reaching the gonads are promoted by chemoattractants secreted from the gonads. Interestingly, migration of primordial germ cells to the correct site still occurs even though formation of the gonads is compromised (Hu et al., 2013; Kreidberg et al., 1993). An explanation for this could be that production of chemoattractants in not only the gonads but also the adjacent mesentery and mesonephros is sufficient to guide the migrating primordial germ cells to their final destination.

After primordial germ cells reach the gonads, they cease migration and begin to form cell-to-cell associations with the somatic cells. It is hypothesized that reaching the site of highest concentration of the chemoattractants prompts primordial germ cells to stop migrating (Richardson and Lehmann, 2010). In addition, gonadal somatic cells likely suppress primordial germ cell migration, but the molecular mechanisms are not known. In the fetal testis, primordial germ cells become surrounded by Sertoli cells, which are responsible for the formation of testis cords. While they are enclosed in the testis cords, germ cells undergo rapid proliferation, form aggregates called germ cell cysts, and then cease mitosis (Lei and Spradling, 2013). Germ cell development that follows formation of fetal testes is discussed in detail in the following article on spermatogonial development and spermatogenesis.

Male Sex Determination—Phenotypic

Gabriel Livera, CEA – INSERM – Universities Paris 7 and Paris 11, Fontenay-aux-Roses, France

The male sex determination is a sequential process that starts during fetal life in mammals. The building of the testis from the undifferentiated bipotential gonad is the process central to establish the male characteristics in the embryo and later. The somatic cells of the male gonad will impose the spermatogenic fate to the neighboring germ cells and act on distant tissues through hormone production to virilise the reproductive tract and other organs. The formation of testes in the embryo is thus key for the establishment of maleness. During fetal life, the proper differentiation of the testis is not only mandatory for allowing the sperm production later, in adulthood, but also to permit the masculinization of the fetus with the development of appropriate reproductive organs both intern and extern.

Testicular Differentiation

Before the testes acquire their adult oval-shape, side by side with the epididymides, in a scrotal position they undergo a developmental process starting with two long fine threads that occupy most of the abdominal cavity, the undifferentiated embryonic gonads. The many cell types of the testis are all formed early during development with a fast and sequential sequence of differentiation (Svingen and Koopman, 2013). In mammals, this sequence is usually initiated during the first third of the gestation. The testis comprises various somatic cells and germ cells and all have to acquire a male fate during development. However, it is only the testicular somatic cells, more specifically the Sertoli and Leydig cells, that are required to properly masculinize the embryo (Fig. 1).

The gonad appears first as an anlage on the ventral face of the mesonephros, a primitive kidney present during embryonic development in mammals. The thickening of it due to cell proliferation and migration of various cell types, including the primordial germ

cells, will result in an undifferentiated bipotential gonad. Such can be observed at 11.5 days post-conception (dpc) in the mouse and 5 weeks post fertilization (wpf) in humans. The gonads then contain the bipotential precursors of somatic and germ cells.

Shortly after, in XY embryo, testicular cords form (Nel-Themaat et al., 2009). This is the first morphological event that allows distinguishing a testis from an ovary. It relies on the differentiation of the Sertoli cells. The first Sertoli cells can be observed as early as 12.0 dpc in the mouse testis and about 6 wpf in humans. Embryonic Sertoli cells are the conductor of the male sex determination. These cells will provoke the rapid appearance of the steroidogenic testicular cells, the Leydig cells, as soon as 12.5 dpc. They also trigger the differentiation of the peritubular myoid cells surrounding the cords and impose the male fate to the germline.

Testicular Cords

The gonadal anlage results from a thickening of the coelomic epithelium due to cell proliferation and migration. These cells are believed to be the precursors of the somatic lineages in the genital crest. Interestingly the XY embryonic gonad grows slightly thicker than its XX counterpart from then on.

Sertoli cells are the first to differentiate within the future testis (Magre and Jost, 1991). These cells provide support and protection to the male germline and are thus termed supporting cell lineage. In the mouse embryo, around 12.5 dpc, Sertoli cells that have differentiated polarize and aggregate to surround groups of germ cells. The tube-like structures then created are the testicular cords, the rudiments of the seminiferous tubules that will be observed in the adult testis. The simultaneous formation of several cords has been demonstrated to be a two step process: first, a large bundle of Sertoli and germ cell formed, second it is partitioned in cord-forming units due to its fractionation by cells migrating from the mesonephros toward the coelomic epithelium (Cool et al., 2012). Sertoli cells do proliferate actively during the fetal life and cease progressively multiplying during post-natal life. In the mouse, Sertoli cell proliferation is almost null around 15 days postpartum (dpp) (Vergouwen et al., 1991). Thus the fetal and post-natal multiplication of Sertoli cell is key to establish the testicular size. Indeed it is accepted that each Sertoli cell can only support a given number of germ cells in the adult testis.

Myoid cells surround the testicular cords, forming an additional outer layer. These peritubular cells appear at 13.5 dpc in the mouse and aggregate around Sertoli cells. Then, they rapidly elongate and flatten. At 14.5 dpc, peritubular cells start expressing markers of smooth muscular cells such as alpha smooth muscle actin (α -SMA). In the human, peritubular cells are morphologically recognizable at 12 weeks of gestation. Together with Sertoli cells they will produce a basement membrane or basal lamina (Merchant-Larios and Taketo, 1991). In the adult peritubular myoid cells display a contractile function needed to allow sperm progression in the tubules.

The Sertoli cells develop tight junctions between adjacent cells. This is part of what is called the blood testis barrier (BTB). Such BTB is a structure required for the proper progression of spermatogenesis. In the mouse the BTB is set up between 15 and 20 dpp. This coincides with the period when a lumen appears in the testis cords; then these are not anymore cords but tubules. This transformation of testis cords in seminiferous tubules is a mark of their terminal differentiation, albeit these do not produce yet sperm cells. The tubular diameter will progressively increase to accommodate the developing seminiferous epithelium until adulthood.

Vascularization

The embryonic testis displays very early a specific vasculature. The embryonic gonads contain numerous microcapillaries and in the case of the embryonic testis a blood vessel becomes visible very early on the ventral part of the gonad just beneath the epithelium (Brennan et al., 2002). This male-specific coelomic vessel will be the future spermatic artery. It likely originates from the cells that migrated from the mesonephros as these bear endothelial cell markers and are thus believed to form the vasculature of the gonadal primordium. The distinctive coelomic vessel can be observed in the male fetal gonad by 13.5 dpc. The specific arterial system set up in the male embryonic is believed to facilitate the proper exportation of male hormones.

Leydig Cells

The interstitial tissue, in-between the cords, contains the Leydig cells that are responsible for the production of androgens. Fetal Leydig cells form a population distinct from the adult ones. Fetal Leydig cells appear just after initial sex differentiation and induce masculinization of the fetus by producing androgens (Habert et al., 2001). Leydig cell number increases throughout fetal life from about 200 at 12.5 dpc up to more than 10,000 in the new-born mouse. At the same time, those cells progressively increase in size and aggregate forming clumps often near or around blood vessels. Leydig cells produce testosterone as early as they differentiate and testosterone production peaks about 17.5 dpc in the mouse, and 14 wpf in humans (Livera et al., 2006). These androgens will be mandatory for the masculinization of the fetus. Of interest, fetal Leydig cells differ from the Leydig cell population observed in the adult testis. Indeed, at puberty a new population of adult Leydig cells will replace earlier populations. These later have small and relatively fewer cytoplasmic lipid droplets in comparison to fetal Leydig cells (Haider et al., 1995). Fetal Leydig cells in rodents can produce testosterone independently of luteinizing hormone stimulation (LH), while adult Leydig cells heavily depend upon LH stimulation. This appears untrue in the case of human fetal Leydig cells that are literally bathed in chorio-gonadotropin (LH analog). Perhaps the best criterion differentiating fetal Leydig cells from their adult counterpart is their ability to respond to multiple LH-stimulation without desensitization. This feature likely accounts for their formidable androgen production. Of note, fetal Leydig cells also produce another hormone required for proper masculinization (INSL-3).

Germ Cells

During fetal life, the testis contains exclusively mitotic germ cells, the meiotic and post-meiotic cells will only be formed after birth with meiotic onset at puberty. The germ cells are not formed within the embryonic gonad but originate from outside. The primordial germ cells (PGC) migrate from a region quite distant from the gonads, being at the base of the allantois at 6.5 dpc. After a long journey, germ cells finally reach the genital crests around 10 dpc. At that time they are termed post-migratory PGCs, they actively proliferate and are often observed with patches of condensed chromatin in their nuclei. In the rodents, once included in testis cords, germ cells will progressively stop dividing. Then they are often referred as “gonocytes” (Culty, 2009). The exact reason for this mitotic arrest is unknown though it has been hypothesized that it may facilitate epigenetic events occurring then. The quiescence phase of gonocytes starts from 14.5 or 15.5 dpc and lasts up to birth in the mouse. At that time gonocytes are easily recognized due to their large spherical nuclei containing fine chromatin granules and often two globular nucleoli. In the human testis no quiescence phase has been reported possibly due to the lack of synchronicity of the human germline during development. During the beginning of postnatal life, in rodents, the gonocytes relocate progressively from the center of the cords to the basement membrane. This will also be the place homing the future spermatogonia that derived from the gonocytes. The transition from gonocyte to a prespermatogonial type in contact with the basement membrane occurs before birth in humans.

Masculinisation of the Reproductive Tract

Internal and external genitalia develop after the testicular differentiation. The internal reproductive organs are—apart the testes—the epididymis, the vas deferens and the accessory glands (seminal vesicles, prostate and bulbourethral glands). The epididymis is a long duct connected to the seminiferous tubules in its anterior part (head) and in which sperm will mature. The vas deferens is the portion of tube connected to the posterior end of epididymis (cauda). The accessory glands provide fluids to lubricate the duct system and sustain the sperm. This forms the reproductive tract that passes the sperm from testes up to the ejaculation. The external genital organs are the penis and the scrotum, a pouch-like structure holding the testes below the body wall.

Internal Genitalia

Unlike the gonads, the male and female reproductive tracts originate from different primordia. Prior to sex determination, embryos contain two complete sets of ductal structures. The male genital tract arises from the Wolffian ducts and the female one from Müllerian ducts (Rey et al., 2000). Those ducts are also termed respectively mesonephric and paramesonephric ducts due to their position in the mesonephros bordering the gonad. In the male embryo, the primordium of the female tract, the Müllerian ducts, will disappear while the primordium for male tract will develop. The regression of the Müllerian duct is due to the anti-Müllerian hormone (AMH) production by Sertoli cells during development. Androgens produced by fetal Leydig cells actively maintain Wolffian ducts, which give rise to the epididymis, vas deferens and seminal vesicles. The external genitalia differentiate from the urogenital sinus. External genitalia define the sex for the civil status in the human species.

The two pairs of ducts co-exist in the mesonephroi in both sexes at the beginning. The Wolffian duct appears as a continuous tube that runs the length of the urogenital ridge. Thus the Wolffian duct is present all along the mesonephros; it is nearby the Müllerian duct. Wolffian ducts open in the urogenital sinus at the most posterior end of the embryo.

The first event evidencing a male differentiation of the reproductive tract is the regression of the Müllerian ducts. This regression is observable at 14 dpc in the mouse male embryo and at 8 wpf in human ones (Dyche, 1979). These have almost completely disappeared by 9 wpf. Second, shortly after, due to the development of the definitive kidney (metanephros) and under the action of androgens the Wolffian ducts will give rise to the male reproductive tract. This witnesses a functional change from urinary to reproductive function. Testosterone allows the stabilization and the differentiation of Wolffian ducts (Welsh et al., 2007). The main organ resulting from this differentiation is the epididymis. The formation of the epididymis involves a complex program to achieve the formation of a long tube with a complex pattern of coiling, formation of septae, and regional functionalization. The cranial part of the duct become connected to the testis cords forming the rete testis and the portion of the duct just below tremendously elongate and becomes convoluted to form the epididymis. The caudal part of the duct will develop a muscular envelope and form the vas deferens. In the most distal part of each duct, just prior the junction with the sinus, a lateral diverticulum will grow and produce the seminal vesicle. Thus the main internal accessory reproductive organs are all derived from the Wolffian ducts. The prostate and bulbourethral gland originate from the differentiation of the urogenital sinus (Table 1).

Pioneer studies by Alfred Jost evidenced that in utero castration of rabbit fetuses prior to sexual differentiation systematically triggered a female-type development of the genitalia (Jost, 1953). This demonstrated that only testicular hormones are key for both the regression of the Müllerian ducts (AMH) and the development of Wolffian ducts (testosterone).

External Genitalia

The external genital differentiation is also profoundly stroke by the presence of testicular androgens (mostly dihydro-testosterone in this case). The external genitalia differentiate from a bipotential anlage composed of the genital tubercle, folds and outer swellings that remain sexually undifferentiated until 9 wpf in human embryos (Yamada et al., 2003). Then male specific change will appear

Table 1 Chronology of the main events during male differentiation

	<i>Mouse</i>	<i>Human</i>
Formation of the gonadal primordium	10 dpc	4 wpf
Colonization by the primordial germ cells	10.5–11.5 dpc	4–5 wpf
Formation of testicular cords	12.5 dpc	7 wpf
Differentiation of Leydig cells	12.5 dpc	8 wpf
Regression of Müllerian ducts	14 dpc	8 wpf
Masculinization of external genitalia	16 dpc	10 wpf
Appearance of seminal vesicle	16 dpc	10 wpf
Appearance of prostatic buds	17 dpc	10 wpf
Increased anogenital distance	16 dpc	11–13 wpf
Fully descended testes	25 dpp	30 wpf

dpc, days post-conception; *dpp*, days post-partum; *wpf*, weeks post-fertilization.

Modified from Saint-Dizier M. & Chastand-Maillard S: *La reproduction animale et humaine*. (2014) Chapter 1: p. 19–39. Quae, Versailles, France.

with a near-complete male phenotype observable at the beginning of the second trimester (14 wpf). The genital tubercle elongates and grows to form the penis. The folds located below, on each side of the urethral groove, will close over the groove. The swellings on the outer sides of the folds, also referred as labio scrotal ridges, will form a pouch to later accommodate the testes, the scrotum. As the scrotum forms, testes descend down the posterior abdominal wall, through the inguinal canal. This descent is a long process starting around 10 wpf and usually completed around 30 wpf. Testicular descent also depends on androgen and on another Leydig cell secretion the insulin-like 3 (INSL-3). Testicular descent is decomposed in a two phases process with INSL-3 mediating the first part, trans-abdominal, and androgens mediating the second part, inguino-scrotal (Klonisch et al., 2004). In mice, testicular descent is mostly post-natal and completed by 25 dpp. This extra-abdominal position of the testes provides them with a temperature lower than the body temperature, a difference mandatory for proper spermatogenesis. However, one should keep in mind that not all mammals have descended testes.

Male Determination of Other Tissues

The development of male-specific features is obviously not only restricted to the gonads and reproductive tract, albeit studies and consensus remain scarce in other tissues. The perineal growth and the digit ratio are indicators that have been promoted as markers of virilisation. The brain evidently is also primed differently in males and females. Though this is far from exhaustive other parameters have not yet received detailed attention.

The development of the genital tubercle and genital swellings into, respectively, the penis and scrotum is accompanied by an increase in perineal growth and thus a longer anogenital distance (distance from the anus to the posterior base of the genital tubercle). This distance is longer in males than in females in most mammals (twice as long in rodents) (Welsh et al., 2008). As this feature is easy to observe at birth, it is often used as a marker of the proper exposure to androgens and proper masculinisation during fetal life.

The ratio of the lengths of the index and ring finger (2D,4D digit ratio) has been proposed as another marker of androgen action during development in mice and humans (McIntyre, 2006). Males have generally a longer ring finger (digit 4) relative to the length of index finger (digit 2) than females. This parameter is quite attractive as it is easy to measure though it remains debated.

Sexual dimorphism of brain structures has been reported in various species. This sexual differentiation of the brain induces neuroanatomical changes that are believed to impact behavior. However many environmental factors also shape the brain and this complexity has limited a clear view of what is due to a direct hormonal effect. Maybe one of the best examples that male and female brains differ at the anatomical level is the existence of a nucleus in the rat brain with a different size according to the sex, the “sexually dimorphic nucleus of the preoptic area” of the hypothalamus (Gorski et al., 1978). In the male rat the volume of this structure is about three to eight times larger than in females and this sexual difference is mostly established during post-natal development. This structure is implicated in sexual behavior in animals. The volume or neuron number has since been reported to differ in numerous other areas of the brain albeit many variations in species exist. Lastly, early differences observed between the XX and XY embryonic brains (prior testicular steroidogenesis) also point toward likely cell-autonomous events possibly related to the chromosomal constitution. This possibility that some male features might rely on cell-autonomous events (not being the consequence of having testes) is similar to what has been reported in marsupials, where the formation of a scrotum, or a pouch, is a consequence of the absence or presence of two X chromosomes.

Anecdotally, the mammary gland development differs according to the sex in some mammals but not in others. Though in humans, at birth, roughly similar mammary structures are observed in boys and girls, in rats and mice, the post-natal mammary structures appear strikingly different. In the rat fetus, the mammary anlage shows a male-specific atrophy of the rudimentary buds. This suppresses nipple formation during post-natal life, another parameter often used to monitor proper masculinisation, albeit exclusively in rodents.

In conclusion, the testicular development is key to maleness acquisition. The hormonal secretions of the developing testis ensure that the development of the gonad is properly coordinated with that of the rest of the organism to ensure the complete establishment of the male reproductive potential once adult. Testicular androgens are the main endocrine factors promoting masculine phenotypes. A period of high testosterone production in males during the fetal life drives the differentiation of primary reproductive tissues. Nevertheless, the particular pattern of testosterone production varies among vertebrate species and differences in potential target tissues are widely debated.

SRY: The Y-Linked Mammalian Testis-Determining Gene

Primary sex determination describes the process by which the embryonic gonad develops as a testis or ovary. Subsequent to this, the phenotypic sex of the fetus, including the anatomy of the internal and external genitalia, is established by hormonal products of the gonads (or the absence thereof). In mammals, the Y chromosome is a dominant male determinant. *SRY* is the gene found on almost all mammalian Y chromosomes that is responsible for initiating testis determination during embryonic development. *SRY*, which encodes an HMG box transcription factor, is expressed in somatic supporting cell precursors and initiates a pathway of gene expression that results in the differentiation of Sertoli cells (Larney et al., 2014). Thus, sex determination is a matter of controlling the fate of the supporting cell lineage in a sexually dimorphic fashion. Other morphogenetic processes required for testis development, such as the formation of testis cords and associated vasculature, and the differentiation of Leydig cells, are thought to depend on Sertoli cell signals. In the absence of the Y chromosome, ovary development ensues due to pro-ovarian pathways of gene expression.

In the mouse, the mammalian species in which the molecular mechanisms underlying gonad development have been most intensively studied, *Sry* expression exhibits exquisite control. It is first detected at around 10.5 days *post coitum* (dpc) in somatic cells, approximately 24 h after the formation of the gonadal primordium. Expression is initiated at the center of this long thin organ and by 11.5 dpc, at its peak, expression has spread to the gonadal poles. By 12.5 dpc, *Sry* expression is extinguished. This dynamic spatiotemporal profile is related to its function: *SRY* is only required at early stages of gonad development to initiate Sertoli cell differentiation, partly by repressing ovarian pathways of development (see sections **Sox9: Conserved Master Regulator of Testis Determination** and **FGF9: Propagating the Testis-Determining Signal**); but it is not required to maintain Sertoli cell identity. That role is performed by another HMG box transcription factor encoded by *SRY*'s principal target gene, *SOX9* (see section **SOX9: Conserved Master Regulator of Testis Determination**) and another transcription factor, *DMRT1* (section **The "Battle of the Sexes": A Life-Long Struggle**).

A number of studies in the mouse reveal that, depending on genetic background, a significant delay in the expression of *Sry* can result in complete or partial gonadal sex reversal, that is, XY ovary or ovotestis development (Carre and Greenfield, 2014). These observations underline the requirement for timely expression of *SRY* to oppose ovarian developmental pathways: a 'window of opportunity' exists for *SRY* and it must not miss it (Hiramatsu et al., 2008). A delay to, or reduction in, *Sry* expression at this critical time-point can arise following mutation in some key regulatory genes, such as *Insr/Igf1r*, *Wt1*, *Gata4/Fog2*, *Cbx2*, *Six 1/4*, *Jmjd1a*, *Map3k4*, and *Gadd45g*. Such genes may act to directly enhance the transcription of *Sry*, or promote proliferation of *SRY*-positive somatic cells, or both. Mutation in human genes required for normal *SRY* expression may account for a large number of cases of 46,XY partial or complete gonadal dysgenesis (CGD), namely XY female development (Bashamboo and McElreavey, 2015). Mouse mutant models offer a way of investigating molecular mechanisms that underlie such human disorders of sex development (DSDs) (Table 1). However, the mouse and human sex-determining networks are not identical. *GADD45γ* is a key regulator of mouse *Sry*, through its activation of *MAP3K4*, but no human *GADD45g* mutations are reported (Bogani et al., 2009; Warr et al., 2012). However, whilst no human *MAP3K4* mutations have been reported in 46,XY DSD, mutations in the related gene, *MAP3K1*, do disrupt human testis determination (Pearlman et al., 2010).

In the absence of *SRY*, in XX embryonic gonads, ovary development ensues. Ovarian development is characterized by the absence of Sertoli cells and testis cords; instead, pregranulosa cells (the homologous ovarian supporting cell lineage) form and, along with germ cells, organize into ovigerous cords at around 13.5 dpc in the mouse. At around birth these ovigerous cords form primary follicles, containing a single oocyte surrounded by layers of granulosa cells and then theca (steroidogenic) cells. Alternative genetic pathways predominate in the XX gonad and direct development towards an ovarian fate. Canonical WNT/ β -catenin signaling is one major pro-ovarian pathway, requiring genes such as *RSPO1*, *WNT4*, and *CTNNB1* (Chassot et al., 2014). This pathway is implicated in ovary development in mice and humans. A key pro-ovarian transcription factor is *FOXL2* (Pannetier et al., 2016). Again, this factor is implicated in ovarian development and function in humans, mice and goats (see section **The 'Battle of the Sexes': A Life-long Struggle**).

SOX9: Conserved Master Regulator of Testis Determination

A wealth of genetic data in humans and mice has established an over-arching role for *SOX9* in testis determination (Jakob and Lovell-Badge, 2011; Warr and Greenfield, 2012). Indeed, evidence exists implicating *SOX9* in testis development in vertebrates more broadly. Human patients with campomelic dysplasia and 46,XY gonadal dysgenesis, resulting in sex reversal, were the first cases reported to have mutations in *SOX9* (Foster et al., 1994). Mouse studies then showed that inactivation of *Sox9* by gene targeting caused complete XY gonadal sex reversal (Barriónuevo et al., 2006). Moreover, forced expression of *Sox9* in XX gonadal somatic cells at around the time of sex determination resulted in testis development. These data suggest that *SOX9* activity is both necessary and sufficient for testis determination. *SOX9* is a transcription factor that has been shown to be required for the

Table 1 Mouse and human gonadal phenotypes associated with mutations in testis-determining genes

Gene name/symbol	Mouse mutant phenotype	Human clinical phenotype	References (PMID)
Sex determining region of Chr Y (<i>SRY</i>)	Complete XY gonadal sex reversal in deletion mutant	Point mutations cause 46,XY complete gonadal dysgenesis (CGD)—sex reversal	2401216 2247149
<i>SRY</i> (sex determining region Y)-box 9 (<i>SOX9</i>)	Knockout heterozygotes die around birth; conditional deletion causes complete XY gonadal sex reversal	Loss of <i>SOX9</i> functionality by mutation results in campomelic dysplasia and XY CGD.	15056615 16207837 7990924
Fibroblast growth factor 9 (<i>FGF9</i>); Fibroblast growth factor receptor 2 (<i>FGFR2</i>)	On the sensitized C57BL/6 J background the loss of <i>FGF9</i> by knockout causes fetal XY complete gonadal sex reversal; conditional deletion of <i>FGFR2</i> , or point mutation, also causes partial or complete sex reversal	One report of an individual with craniosynostosis and 46,XY CGD with an <i>FGFR2</i> mis-sense mutation	11290325 17940049 18155190 24956260 26362256
Doublesex and mab-3 related transcription factor 1 (<i>DMRT1</i>)	<i>DMRT1</i> knockout causes infertility and postnatal somatic cell reprogramming of Sertoli cell to granulosa cell-like fate	A report of one individual with 46,XY CGD and a mis-sense mutation in <i>DMRT1</i>	11040213 21775990 26005864
Nuclear receptor subfamily 0, group B, member 1 (<i>NROB1</i>)	Loss of <i>NrOb1</i> (<i>Dax1</i>) on sensitized background causes XY gonadal sex reversal; <i>NrOb1</i> over-expression on sensitized background disrupts testis determination	Altered <i>NROB1</i> dosage thought to be responsible for X-linked dosage-sensitive sex reversal (<i>DSS</i>)	12679814 18633137 9486644 8570694
Growth arrest and DNA-damage-inducible 45 gamma (<i>GADD45g</i>)	Loss of <i>Gadd45g</i> causes complete XY gonadal sex reversal in the fetus and adult	No reports of <i>GADD45g</i> mutations in DSD	23102581 23102580 23516551
Mitogen-activated protein kinase kinase 4, 1 (<i>MAP3K4</i> , <i>MAP3K1</i>)	<i>Map3k4</i> knockout and point mutation cause fetal XY gonadal sex reversal; <i>Map3k4</i> over-expression rescues <i>Tas</i> sex reversal phenotype	No reports of <i>MAP3K4</i> mutations, but a large number of mutations reported in related gene, <i>MAP3K1</i> , in 46,XY DSD	19753101 24452333 21129722 21559298 23102580
Mitogen-activated protein kinase 11, 14 (<i>MAPK11</i> , <i>MAPK14</i>) Chromobox 2 (<i>CBX2</i>)	Double knockout of <i>Mapk11</i> (p38a MAPK) and <i>Mapk14</i> (p38b MAPK) causes fetal XY gonadal sex reversal <i>Cbx2</i> (<i>M33</i>) knockout causes fetal XY sex reversal	No human mutations reported <i>CBX2</i> mutations reported in case of 46,XY CGD	9641679 22186409 19361780

Wilms tumor 1 homologue (<i>WT1</i>)	Targeted deletion of the WT1(+KTS) isoform causes complete XY gonadal sex reversal through disruption to <i>Sry</i> expression	<i>WT1</i> mutations reported in Frasier Syndrome patients with sex reversal	11509181 19549635 12932885 24009392
Lysine (K)-specific demethylase 3A (<i>KDM3A</i>)	Loss of <i>KDM3A</i> (<i>JMJD1A</i>) on a sensitized background causes XY gonadal sex reversal	No reports of human mutations	
GATA binding protein 4 (<i>GATA4</i>)	Loss of <i>GATA4</i> causes XY gonadal sex reversal due to disruption to <i>Sry</i> and <i>Sox9</i>	<i>GATA4</i> mutations reported to disrupt human testis determination	17848526 21385577 21220346
Zinc finger protein, multitype 2 (<i>ZFPM2</i>)	<i>ZFPM2</i> (<i>FOG2</i>) acts together with <i>GATA4</i> to control testis determination	<i>ZFPM2</i> mutations reported to disrupt human testis determination	17540364 21385577 24549039
Desert hedgehog (<i>DHH</i>)	<i>Dhh</i> knockout on a mixed genetic background causes infertility and failure of Leydig cell specification	A number of reports of <i>DHH</i> mutations in 46,XY DSD, including CGD	12050120 25927242

expression of a number of genes in the developing testis, including *Amh*, *Vanin-1*, *Ptgsd*, and *Cyp26l1*. In fact, genome-wide chromatin immunoprecipitation experiments (ChIP-seq) indicate that SOX9 binds thousands of target genes, including most of those already implicated in testis determination (Rahmouni et al., 2017). It remains unclear how many of these are positive targets, up-regulated by SOX9, and how many are negative targets. Nor is it known whether SOX9 functions at all regions to which it is recruited. As with many genome-wide approaches, subsequent focused functional studies will be needed, in this case to determine precisely which SOX9 targets function in testis development. It will also be important to understand the relationship between SOX9 and other SOX proteins that have been implicated in testis development, such as SOX8, SOX10, and SOX3. The compensatory actions of such orthologues might complicate the mechanistic insights offered by the study of knockout phenotypes.

In the mouse, SOX9 can be detected in somatic cells from early stages of gonad development, initially in both XX and XY gonads. It is then down-regulated in the XX gonad and up-regulated in XY gonad, such that by 11.5 dpc expression is effectively restricted to the XY gonad. The hypothesis that SRY might regulate the expression of *Sox9* is supported by a number of observations, including co-expression of both genes in the nuclei of supporting cell precursors, their shared function in testis determination and, crucially, the fact that *Sry* expression precedes that of *Sox9*. Chromatin immunoprecipitation of SRY in mouse embryonic gonads identified a region around 15 kb from the transcriptional start-site of *Sox9* that was bound by SRY, known as TES (Sekido and Lovell-Badge, 2008). The core region of this putative enhancer element, termed TESCO, is capable of driving expression of a *lacZ* reporter gene in an XY-specific fashion in transgenic embryonic gonads. In cell transfection assays the activity of the enhancer is enhanced by the joint recruitment of both SRY and SF1 (NR5A1), a transcriptional co-factor known to be important in gonad formation and subsequent differentiation. These data and other reports support a model in which SRY and co-factors bind to the TESCO enhancer from around 10.5 dpc, resulting in up-regulation of its expression. In the absence of SRY, no such up-regulation occurs and ovary development ensues. Data also support a role for SOX9 in binding to its own gonadal enhancer and maintaining its own expression and effectively 'locking in' Sertoli cell identity. SOX9 remains a marker of Sertoli cells in the testis throughout the life of an individual.

The phenotypic consequences of genetically ablating TES and TESCO have been examined using CRISPR/Cas9-mediated genome editing (Gonen et al., 2017). Loss of either element does not lead to a loss of *Sox9* expression and XY gonadal sex reversal as a consequence. Rather, *Sox9* expression is down-regulated: to 62% of wild-type levels at 14.5 dpc in embryos lacking TESCO, and 44% wild-type levels in those lacking TES at 13.5 dpc. Only in the context of another genetic insult does the loss of either element overtly disrupt the phenotypic course of testis development. These data suggest that another *Sox9* gonadal enhancer (or enhancers) exist that can operate adequately in the absence of TES/TESCO. The identity of these is currently unknown, although alternative regions upstream of the TSS, putatively required for expression of human SOX9, have been reported (Gonen et al., 2017). It is a well-founded prediction that any other functional *Sox9* enhancers will also be bound by SRY, but this will need to be tested in vivo.

FGF9: Propagating the Testis-Determining Signal

The role played by certain genes in sex determination is occasionally identified by serendipitous discovery in a mouse knockout, rather than on the basis of an inviting expression profile or a case of human sex reversal. Embryos lacking the fibroblast growth factor FGF9 exhibit severe lung and limb defects. They also exhibit complete gonadal sex reversal when bred onto the C57BL/6J genetic background (Colvin et al., 2001). This genetic background is known to be sensitized to disruptions to testis determination. Careful examination of gonads from FGF9-deficient embryos revealed that whilst *Sox9* was initially up-regulated as normal in the mutant XY gonad, high levels of *Sox9* were not maintained and expression was gradually lost by 12.5 dpc (Kim et al., 2006). Loss of the pro-testis program of gene expression results in activation of the ovarian program. Interestingly, expression of *Fgf9* was also shown to be lost in XY gonads lacking SOX9. This observed mutual dependence resulted in a model in which SOX9 acts to positively regulate *Fgf9* expression and then FGF9 in turn acts, through its receptor FGFR2, to positively enforce *Sox9* expression: a positive feedback loop. As predicted, loss of FGFR2 itself also causes XY gonadal sex reversal in mice.

The details of this model were called into question when gonad development was examined in mutants lacking both FGF9 and the pro-ovarian signaling molecule, WNT4 (Jameson et al., 2012a). Mutual antagonism between WNT4 and FGF9 had been established by studying gonad development in mutants lacking either gene: XY gonads lacking FGF9 ectopically express high levels of *Wnt4*; XX gonads lacking WNT4 exhibit high levels of *Fgf9* (Kim et al., 2006). These data suggest that in the absence of one of these proteins, sex reversal occurs due to the loss of inhibitory signals that normally oppose the other pathway. When XY embryos were generated lacking both proteins, testes developed. This observation suggests that the primary role of FGF9 in the XY gonad is to repress the anti-testis activity of WNT4; when WNT4 is absent, FGF9 is not required for SRY/SOX9 to initiate and maintain testis development. It is worth noting that the relationship between FGF9 and WNT4 is not, however, symmetric: loss of both proteins in XX gonads does not rescue the partial female-to-male sex reversal phenotype of WNT-deficient XX gonads. Moreover, the molecular nature of this genetically-defined opposition between FGF9 and WNT4 is unclear.

FGF9 is a secreted growth factor that acts in a paracrine fashion to reinforce the cell-autonomous activities of the transcription factors SRY and SOX9. Studies of testis development in vitro, using organ culture methodologies, have been invaluable in dissecting the pathways required for testis determination and have permitted the identification of the cellular process of mesonephric endothelial cell migration as fundamental for the development of testis cords and associated vasculature. Two questions that arise are: how does the testis-determining signal initiated by SRY expression at the center of the gonad spread to the poles, and why is there no appreciable delay in the formation of testis cords at the poles versus the center? Independent culture of XY gonadal

segments (center and poles) in vitro reveals that *Sox9* expression is not maintained in polar tissue when separated from the central segment and testis cord formation is disrupted as a consequence (Hamamatsu et al., 2010). Reconstruction and partition experiments showed that rescue of these defects is not dependent on cellular movement from the center of the gonad; rather, the critical role of the central domain can be substituted by the supply of exogenous FGF9. *Fgf9* expression itself is first detected in the center of the gonad at the 15–16 tail somite stage. These data suggest that FGF9 acts as a rapidly-acting, poleward diffusible factor in XY gonads that promotes testis cord formation via its positive effects on *Sox9* expression. Interestingly, despite FGF9's established role in opposing the pro-ovarian activity of WNT4, reducing levels of WNT4 in XY gonads, using heterozygous *Wnt4* mutant gonads, did not alter the reduced tubulogenic capacity of polar segments.

In acting to support and reinforce the expression of SOX9, FGF9 is functioning in a similar way to another molecule, prostaglandin D2 (PGD2). PGD2 also amplifies SOX9 expression in Sertoli cells—and acts to promote recruitment of cells to the Sertoli lineage—and this hints at the existence of back-up gene networks that exist to buffer the testis-determining signal from disruption (Wilhelm et al., 2005). Along with the antagonistic roles that testis-determining genes play, this buffering likely reflects the potential peril associated with initiating testis or ovary development in a single bipotential primordial, one in which there is expression of molecules from both the testis- and ovary-promoting pathways at early stages. Functional redundancy is also a familiar theme in the study of sex determination, and the roles of certain molecules are sometimes only revealed when other compensating family members are inactivated simultaneously. These genetic mechanisms ensure the canalization of male or female gonad development from a bipotential primordial.

The “Battle of the Sexes”: A Life-Long Struggle

Despite the observation of mutual antagonism between individual pro-testis and pro-ovary gene pairs, such as in the case of FGF9 and WNT4, and SOX9 and RSPO1, it is perhaps best to see the testis- and ovary-determining gene regulatory networks as opposed at multiple points (Fig. 1). Indeed, it is by the very nature of a sex-determining gene that when it is inactivated, complete or partial sex reversal is caused by the ectopic activation of the alternate pathway, establishing the normal inhibitory role of the inactivated gene. There is a sense in which all testis-determining genes that have been characterized are also anti-ovary genes: it is this that accounts for male-to-female gonadal sex reversal. In the case of ovary-promoting genes such as *Wnt4*, *Rspo1* and *Foxl2*, the sex reversal that arises after deletion is only partial, suggesting a greater complexity in the pathways, molecular and cellular, that establish ovarian identity. The molecular basis of the opposition between SRY–SOX9–FGF9 and RSPO1–WNT4–FOXL2 is not well understood, and much research remains to be done to delineate all the points of contact between these pathways. It is highly likely that this will also require the identification of novel testis- and ovary-determining genes.

Fig. 1 Mutual antagonism between the testis- and ovary-determining networks. The testis-determining gene regulatory network (SRY–SOX9–FGF9/FGFR2) is shown in the upper (light green) arrow; the ovarian network (RSPO1/WNT4/β-catenin–FOXL2) is shown below in the darker green arrow. Arrows indicate positive regulatory relationships, whilst hammered lines indicate negative interactions. Question marks indicate knowledge gaps, some of which are addressed in the main text. In XY gonadal somatic cells, the testicular pathway results in Sertoli cell (SC) differentiation, which drives testis morphogenesis. This pathway is initiated by SRY activity: *Sry* expression is itself regulated by a set of genes (at the edge of the yellow segment). In the absence of SRY, the pro-ovarian pathway drives granulosa cell (GC) differentiation and ovary formation.

The antagonistic actions of the testis- and ovary-determining gene networks were at one point thought to be required only to establish the fate of the developing testis or ovary during the fetal period. However, conditional gene targeting experiments in mouse adult gonads indicate that the requirement to antagonize opposing pathways in sex identity operates even in adult gonadal lineages. The ubiquitous deletion of FOXL2 in the adult XX ovary at 8-weeks of age results in granulosa cell reprogramming consistent with sex reversal around 3 weeks after ablation (Uhlenhaut et al., 2009). Typical follicular structure is lost and seminiferous tubule-like structures replace them. Cells with the morphological characteristics of Sertoli cells appear and express familiar markers such as *Sox9* and *Dmrt1*. These cells are associated with nearby Leydig-like cells that produce testosterone. ChIP data show that FOXL2 can bind to the *Sox9* enhancer, TESCO, and in vitro transfection assays suggest that FOXL2 can repress TESCO activity. Overall, these data suggest that maintenance of ovarian identity requires continuous expression of FOXL2, which actively represses *Sox9* expression. It is perhaps not surprising that the loss of the pro-testis factors DMRT1 and SOX9 in the adult testis can likewise result in male-to-female sex reversal. Loss of DMRT1 results in up-regulation of FOXL2 and reprogramming of Sertoli cells to a granulosa-like cell identity. In this environment, theca cells appear that produce oestrogen and germ cells become feminized (Matson et al., 2011). It will be important to determine whether this interesting and unexpected plasticity of the adult supporting cell lineage is unique and, if so, whether it simply reflects the common embryonic origin of testicular and ovarian somatic cells or some other property or function of this lineage.

Studying the Transcriptome and Epigenome of Gonadal Somatic Cells

This review has so-far adopted a very gene-centric view of the process of sex determination: we have focused on individual testis-determining genes, defined as such by the gonadal sex reversal caused by their inactivation; and we have examined their roles, especially their inhibitory relationships with known ovary-determining genes. There are numerous genes and proteins with a role in gonad development that have not been discussed, mainly due to the limitations of space, but also due to their roles being somewhat 'downstream' of sex-determination, in cellular differentiation and physiology, or due to a role in establishing the fate of lineages other than the supporting cells. In this section, we will take a genome-wide view of the molecular genetics of sex determination: what is known about the transcriptomes of the developing supporting cells at distinct stages, and the epigenomes that underlie them?

Researchers have used expression profiling in the developing mouse gonad for many years, focusing on identifying transcripts exhibiting sexually dimorphic expression, as a means of discovering new candidate sex-determining genes. Experiments have grown in sophistication since early glass-slide microarray experiments that assayed a few thousand genes and newer technologies permit the examination of whole transcriptomes of distinct gonadal cell lineages over several days of development (Jameson et al., 2012b). Such studies are key to understanding the contribution made by specific cell-types to sex determination and the disruption caused by gene mutation or other insults. It is likely that, in the near future, the analysis of single-cell transcriptomes will shed light on the dynamism and heterogeneity of transcriptional control during gonadogenesis.

The molecular basis of differential transcription is attributed to control of the epigenome: the totality of chemical modifications to DNA and its associated histone proteins and RNA molecules that is thought to determine the accessibility of chromatin to transcription factors and the basal transcriptional machinery. Our knowledge of the relationship between dynamic epigenomic events, including long-range interactions between enhancers and promoters, is growing, as is our understanding of how epigenomic marks are deposited, read and erased in distinct cell-types. However, the technologies used to study such events are still in their relative infancy: our ability to determine the epigenomic characteristics of limiting numbers of cells, or in some cases an individual cell, is highly restricted. In this sense, epigenomics is lagging behind transcriptomics. But single-cell approaches in epigenomics promise to shed light on cellular heterogeneity and integration during the establishment of organ fate and this promise is likely to drive the technology forward.

The importance of epigenomic marks to sex determination is clear from XY gonadal sex reversal phenotypes associated with the deletion in mice of two chromatin-associated proteins: the polycomb group protein CBX2 (M33) and the histone demethylase KDM3A (JMJD1A). Sex-reversal in both cases is associated with disrupted *Sry* expression. CBX2 is a component of the polycomb-repressive complex 1 (PRC1), which functions in regulation of gene expression through recognition of methylated histones and methylation of histones. XY gonadal sex reversal in the *Cbx2* KO mouse embryo is rescued by forced expression of an *Sry* transgene, suggesting that other events downstream of *Sry* expression are not disrupted by the loss of CBX2 (Katoh-Fukui et al., 2012). KDM3A, a histone demethylase, is reported to be recruited to the *Sry* locus. Loss of KDM3A on a sensitized genetic background results in XY gonadal sex reversal associated with a significant increase in levels of the inhibitory epigenetic mark H3K9me2 at *Sry* (Kuroki et al., 2013). The authors propose that KDM3A-mediated H3K9 demethylation may induce deheterochromatinization of *Sry*, allowing access to H3K4 methyltransferase and additional transcription factors/co-factors that drive transcription.

Genome-wide characterization of the epigenome of developing gonadal cell lineages is an area of increasing interest, partly because it is now a more tractable task due to improvements in methodologies using very limiting cell numbers. One of the first attempts at such a study reported the analysis of fetal Sertoli cells by DNase1-seq and ChIP-seq for the acetylated histone, H3K27Ac, a mark of active enhancers (Maatouk et al., 2017). Regions of open chromatin, that are putative regulatory sites, are DNase1-sensitive, and DNase1-seq identifies such sites in an unbiased fashion. Sertoli cells purified from the gonad at 15.5 dpc, using FACS, were subjected to DNase1-seq, which identified over 81,000 DNase1 hypersensitive sites (DHSs) at various positions

with respect to nearby genes. One such DHS was found at the *Sox9* gonadal enhancer, TESCO. Similar experiments were also performed at 13.5 dpc and were compared with data from other tissues to identify Sertoli cell-specific DHSs. Interestingly, Sertoli cell DHSs were associated with Sertoli cell- and pregranulosa cell-expressed genes, whilst, as expected, H3K27Ac was enriched near Sertoli cell-expressed genes only. Open Sertoli cell chromatin in the vicinity of pro-ovarian genes may reflect binding of transcription factors that preserve a poised chromatin state or of repressive factors that maintain the Sertoli cell state. The dual use of such regulatory sites to act as repressors in the Sertoli lineage and enhancers in granulosa cells might also underlie the plasticity of the supporting cell lineage discussed earlier. A similar dual-use model applies to TESCO, which is bound by SOX9 in Sertoli cells and FOXL2 in granulosa cells. Further studies, particularly of the chromatin state of pre-granulosa cells, will be required to investigate the generality of this model. Overall, such studies offer a rich resource for identifying novel regulatory elements required for sex determination, some of which will mediate the mutual antagonism of the male and female pathways.

Knowledge Gaps and Future Research

Here, we have reviewed the central role of the testis-determining axis of SRY–SOX9–FGF9, but studies of individuals with unexplained cases of DSDs, including 46,XY CGD and 46,XX testicular DSD, suggest that other genes remain to be identified that play an important role in the specification of the gonadal supporting cell lineage. Moreover, we have not had the space to discuss other molecules whose precise place in the hierarchy of testis determination remains unclear despite a role having been established by knockout studies in the mouse. These include NR0B1 (DAX1), WT1 and GATA4/FOG2. In addition, we have not had space to discuss what is known about the origin and specification of other important testicular cell lineages, such as the interstitial peritubular myoid and Leydig cells. The fate of germ cells in the developing testis and ovary is also an area of intensive investigation.

Finally, novel technologies are likely to transform how we study mammalian testis-determining genes. Genome editing, whole genome/transcriptome/epigenome analyses, the development of cell and organoid models in mice and humans, single cell approaches and mathematical modeling should all allow more rapid progress to be made in our understanding of how genes, gene products and cells interact in space and time in this fascinating multi-lineage organ in order to specify gonadal fate and sexual identity.

Acknowledgments

We wish to thank Rebecca Muir for assistance in the production of Fig. 1. We apologize to colleagues whose research was omitted due to space constraints. Research in the Greenfield laboratory at Harwell is funded by the UK Medical Research Council (MC_U142684167).

Glossary

Adipose tissue Fat tissue; main role is to store energy for the body.

Bone accretion The process of growth of bone, typically by gradual increase over time.

Bone mineral density The amount of bone mineral (such as calcium) within bone tissue.

Estrogen The primary female sex hormone; also plays important roles in male development, including major effects on growth.

Lean body mass The portion of body weight that is not fat (including bone, water, and muscle tissue).

Protein synthesis The process by which protein is made; fundamental aspect of body growth.

Sexual dimorphism A difference in size or appearance between males and females.

Testosterone The primary male sex hormone; plays a critical role in the development of male reproductive tissues, promotes secondary sexual development and influences changes in growth and body composition.

Introduction

Puberty is the period of human development during which sexual maturation occurs. Boys normally begin puberty between 9 and 14 years of age, with an average age of onset of 10 years. In boys, puberty begins when hormonal signals from the hypothalamus and pituitary gland in the brain stimulate the testes to begin producing the hormone testosterone. Testosterone levels rise, leading ultimately to a rapid increase in height, the development of secondary sexual characteristics, and other physical changes. Pubertal progression can be described using standards proposed by Tanner (known as Tanner stages or sexual maturity rating stages). In boys, genital changes are described in five stages, from prepubertal (Tanner stage 1), to fully mature (Tanner stage 5) (Marshall and Tanner, 1970).

The developmental changes that occur during puberty are governed largely by hormonal factors, though environment and genetic factors are also important. The end result of puberty is a striking sexual dimorphism between mature males and females. In addition to gender differences in sexual characteristics, mature males possess more lean body mass and less body fat than females. Males are taller, have greater bone mass and have different body proportions. An understanding of normal pubertal developmental change is important in order to understand when a disease state may be present.

Linear Growth

After a period of relatively stable growth velocity in mid childhood, a significant increase in growth velocity occurs during puberty. This is known as the pubertal growth spurt, and it results in a gain of about 28 cm of height in males (Marshall and Tanner, 1970; Kelch, 1994). In boys, the pubertal growth spurt occurs toward the end of puberty, whereas in girls the growth spurt is an early pubertal event. Thus, boys have a longer period of prepubertal growth than girls, and a boy who is in early puberty likely has significant growth remaining. The difference in adult height between men and women in the United States of 12 cm (roughly 5 in.) is due partly to heights attained prior to puberty (since boys have a longer time period for growth), and partly due to total height gained during the pubertal growth spurt. In boys, peak height velocity is about 11.3 cm/year and occurs at an average age of 13.7 years (compared with 12.1 years and 9.8 cm/year in girls) (Granados et al., 2015). There may be considerable individual variation in these figures as overall health and nutrition, body weight, adiposity, hormonal abnormalities, chronic disease, and family patterns may all influence timing and degree of linear growth.

The onset and control of the pubertal growth spurt depends on a number of hormonal factors (see Table 1). Rising testosterone levels occurring during the time of puberty lead to higher estradiol levels in boys through peripheral conversion of testosterone to estrogen. Testosterone and estrogen (known as “gonadal steroids” since they are steroid hormones produced in the gonads) play a critical role in stimulating growth hormone production. Growth hormone is a major regulator of linear growth, and works primarily by increasing insulin like growth factor-1 (IGF-1) levels. IGF-1 has growth-promoting effects on many tissues throughout the body, including cartilage, bone, and skeletal muscle. Thus, GH and IGF-1 levels increase in puberty in response to rising levels of gonadal steroids. In addition, circulating thyroid hormone produced by the thyroid gland plays an important role in linear growth. Deficiency in any of these hormones may decrease or eliminate the pubertal growth spurt.

The epiphyseal plate (also known as the growth plate) is the portion of the long bone where growth occurs and length is added. Each long bone typically has two growth plates (one on each end of the bone) which are composed primarily of cartilage. Cartilage

Table 1 Hormonal effects on male pubertal growth

<i>Hormone</i>	<i>Primary source</i>	<i>Major effects</i>
Growth hormone (GH)	Pituitary gland	• Promotion of linear growth
IGF-1	Liver	• Stimulation of IGF-1 production
		• Increased protein synthesis
		• Cell growth and proliferation
Testosterone	Testes	• Increased cartilage and skeletal growth
		• Development of secondary sexual characteristics
Estrogen	Converted from testosterone in peripheral tissues	• Promotion of linear growth
		• Bone maturation and increased bone density
		• Cessation of linear growth
Thyroid hormone	Thyroid gland (anterior neck)	• Linear growth and bone maturation
		• Brain development
		• Increased protein synthesis

Styne, D.M. 2016. Disorders of growth, In Styne, D.M. *Pediatric endocrinology: A clinical handbook*. Cham: Springer International, 47–89; Styne, D.M. 2016. Disorders of puberty, In Styne, D.M. *Pediatric endocrinology: A clinical handbook*. Cham: Springer International, 189–232.

cells, or chondrocytes, in the growth plate divide rapidly and ultimately are calcified and converted to bone. This process stops and growth cessation occurs once the chondrocytes undergo programmed cell death under the influence of estrogen. Completed growth is observed radiographically on an X-ray as an epiphyseal line (showing closure of the epiphysis).

Linear growth is accompanied by advancement of skeletal development. This is measured clinically by a study known as a bone age, which looks at development of specific bones in the hand and wrist. As a child progresses through puberty, the bones in the hand and wrist change in a predictable manner; this provides an estimate of skeletal age. The further the skeletal age is from the age of epiphyseal fusion (a bone age of about 17 years in boys), the more growth that remains. For example, a healthy boy with short stature but a delayed bone age likely has significant growth remaining. Alternately, a short boy with a significantly advanced bone age may have very little remaining growth potential.

Body Composition

Progression through puberty is marked by gender specific changes in body composition, which refers to the amount or distribution of fat, bone, water, and muscle in the body. Body composition in a given individual is determined by many factors, and is particularly influenced by nutrition and physical activity. Pubertal changes in body composition are regulated largely by hormonal processes and ultimately result in significant differences between men and women. In early childhood, boys and girls have similar fat mass and fat free mass and prepubertal boys have only slightly more skeletal mass and bone mineral density than prepubertal girls. By the end of puberty, however, boys have significantly more lean body mass and skeletal mass and females have significantly greater fat mass (see [Table 2](#)).

Measurement

A variety of modalities are used to measure body composition. The technique of choice is determined by ease of use, need for accuracy, expense, and degree of radiation exposure.

Field techniques are easy to use and low risk, but generally suffer in terms of accuracy. Body mass index (BMI) is a calculation commonly made in clinical practice, but has major limitations for assessing adiposity in children. Skinfold thickness, measured

Table 2 Overview of pubertal changes in body composition

<i>Trait</i>	<i>Males</i>	<i>Females</i>	<i>Sexual dimorphism by early adulthood</i>
Fat mass	Modest increase	Increases	F > M
Body fat percentile	Stable	Substantially increases	F > M
Muscle mass	Substantial increase	Increases	M > F
Bone mass	Increases	Increases	M > F

M, male; F, female.

using a tool called a caliper, can provide an estimate of adiposity. This is an inexpensive and readily available technique, but is not highly accurate owing to differences in examiner technique and subject variability in age, ethnicity, and gender. Bioelectrical impedance analysis (BIA) is commercially available, noninvasive and portable, and provides a better estimate of adiposity than skinfold thickness. BIA measures electrical impedance (opposition to flow of current through the body), which provides an estimate of total body water. This estimate is then used to determine fat free mass and body fat.

More accurate techniques include dual energy X-ray absorptiometry (DXA), which is highly available and has little radiation exposure. DXA provides a good estimate of bone mineral content and can additionally estimate fat free mass and fat mass. Computed tomography (CT) and magnetic resonance imaging (MRI) allow for accurate calculation of adipose tissue and fat free mass; CT is not routinely used due to concerns over radiation exposure in children. Other techniques are even more accurate, but are reserved for research settings given the specialized equipment and operating expenses required.

Skeletal Development and Bone Density

Total bone mass increases during childhood, with rapid increases in bone mass occurring during puberty. The average age of peak calcium accretion (the time where calcium is laid down into the skeleton most rapidly) is age 14.1 years for boys (Bailey et al., 2000), which occurs about 6 months after peak height velocity in males. Approximately 25%–40% of adult calcium is laid down during the 2 years surrounding the pubertal growth spurt (Bailey et al., 2000; Bailey et al., 1999; Baxter-Jones et al., 2011), making this time period critical for lifelong skeletal health. The major increase in bone mass accumulation occurs in later pubertal stages (Zemel, 2013); males ultimately reach peak bone mass in early adulthood (Berger et al., 2010). Young adult males have greater bone mass than adult females due to overall larger body size.

Many factors influence skeletal development during puberty, including hormonal influences and interplay with other aspects of physical growth. Estrogen plays a critical role in bone maturation and the attainment of normal bone mineral density in both sexes, with effects on new bone formation, bone mineralization, epiphyseal maturation, and establishment of normal skeletal proportions. Other hormones, including androgens, growth hormone, and IGF-1 also contribute to peak bone mass.

Lean body mass also affects bone mineral content, via favorable effects of weight-loading and mechanical strain on bone accretion. Weight bearing, as well as forces generated by muscle contraction, cause bones to adapt their shape and increase density in response to such loads. Fat free mass, as opposed to fat mass, seems to have the major effect on bone development. Obese children have stronger bones, and this appears to be due to effects of increased fat free mass, not their increased adiposity (Sioen et al., 2016). Of note, peak lean body mass accretion appears to occur slightly before peak calcium accretion in boys.

Evaluation of bone mineralization in children is primarily performed clinically through DXA scanning. It is imperative that correct standards for age are used, as comparison to normal adult standards will result in inaccurate reports suggesting low bone density (as young children and adolescents have not yet reached peak bone mass). Pediatric reports utilize z-scores to quantify bone density. These are standard deviation scores which describe how far a given patient's bone mineral density is from matched control values. Caution must be used in interpreting the results, as inattention to the patient's age, gender, ethnicity, and maturity level will result in erroneous values.

Lean Body Mass

Skeletal muscle comprises the majority (>50%) of lean body mass and plays a critical role in movement and locomotion, thermoregulation and metabolism. In early childhood, boys appear to have slightly greater muscle mass than girls, with one study showing 10% greater musculature around the spine in prepubertal boys as compared with girls (Arfai et al., 2002). However, during puberty, this difference becomes pronounced. Boys gain considerable amounts of lean mass and relatively little fat mass during the pubertal years; at maturity, men have about 1½ times the lean body mass (and skeletal mass) of women. Regional differences are also apparent with increased muscularization of the upper body in men compared to women. Men also tend to have greater mass of thigh muscles in front of the femur (as opposed to behind it) compared to women.

Increasing muscular growth in pubertal boys occurs largely as the result of rising testosterone levels. An increase in testosterone stimulates muscle protein synthesis and muscle fiber growth, as well as increased fat breakdown (called lipolysis). Strength is related to muscle size; strength relative to muscle mass is nearly the same in men and women.

Fat Mass

Total fat mass is similar in males and females until just before puberty. During puberty, boys do not significantly change their absolute fat mass. Their percent body fat declines throughout puberty as a result the relatively stable fat mass and increasing fat free mass. By the end of puberty, percent body fat approximates the adult male value of 10%–15% (versus 25% in adult females) (Veldhuis et al., 2005). During puberty, males develop an inverted triangle body shape, with broadening of the shoulders and chest. Fat distribution may become more android in nature, with fat distributed mainly in the abdominal area. This is in contrast to the gynecoid shape (with fat distributed primary on the hips and thighs), which may become more pronounced in females during the pubertal years. Sexual dimorphism in shape is greatest in young adults, and declines with age (Wells, 2007).

Leptin is a metabolically active molecule which acts to regulate appetite and energy expenditure. It is derived from adipose tissue and circulating leptin levels correlate with total fat mass. In prepubertal boys and girls, leptin levels are similar. However, during

puberty, leptin levels decline in males at least partially as a result of increasing testosterone secretion. In females, leptin levels appear to rise under the influence of estradiol. Leptin levels thus exhibit striking sexual dimorphism and are affected by both gonadal steroids and fat mass.

Obesity will result in taller stature in childhood and earlier pubertal development; adult height is not affected. On a population level, the obesity epidemic appears to be leading to early puberty in overweight boys and may be leading to delayed puberty in obese boys. The norms for pubertal timing in males have not yet changed as a result, however.

Brain Development

The brain changes both structurally and functionally during adolescence. The gray matter of the brain, the portion containing the cell bodies, begins a period of increased growth just prior to puberty. During this time period, an increased number of connections form which are ultimately pruned back later in adolescence. This maturation has been described as an inverted-U shaped pattern of development. In the prefrontal cortex, an area of the brain located behind the forehead, this process appears to contribute to increasing impulse control and better judgment in older adolescents as compared with younger ones. The frontal and parietal lobes of the brain attain peak gray matter levels around age 12 in boys (and age 11 in girls), prior to undergoing thinning into adulthood (Giedd et al., 1999). The white matter of the brain is composed of bundles of myelinated axons, which connect gray matter areas and carry nerve signals. White matter volume increases steadily during childhood and adolescence, with males showing greater white matter increases than females (Perrin et al., 2009). Additionally, certain regions of the brain have been shown to develop sexual dimorphism during the adolescent years. Pubertal hormones appear to contribute to this process.

Additional Physical Changes

Primary and Secondary Sexual Characteristics

The first physical change in male puberty is enlargement of the testes. Further growth of the penis and testes, as well as pubic hair development, occur under the influence of gonadal and adrenal hormones. Primary sexual characteristics are present at birth and include the testes and penis in the male. Secondary sexual characteristics are features that develop during puberty but are not directly involved in reproduction. These characteristics may distinguish males from females and arise for the most part due to the influence of pubertal hormones.

Other Changes

In pubertal boys, the larynx, cricoid cartilage and laryngeal muscles increase in size (and the “Adam’s apple” is formed). Vocal cords lengthen and the voice deepens, with abrupt changes in vocal quality occurring between Tanner stage 3 and 4 (Harries et al., 1997). Growth of body hair, including facial, underarm, abdominal, chest, and pubic hair occurs. Sebaceous glands enlarge and sweat production increases due to increased activity of sweat gland. Facial morphology changes, and the male face becomes more square, with more angular features and a relatively larger nose and mandible (jaw bone). Hands and feet become relatively larger as well. Enlargement of the penis and testes occur as noted above.

Conclusion

Puberty is a time of major developmental change in males. Changes in body composition, linear growth and sexual development all result in significant sexual dimorphism by the end of puberty. These changes are largely regulated by endocrine factors.

Functional Organization of the Testis

Testis is the male reproductive gonad. It yields two main functions: the production of testosterone, the male sexual hormone, and sperm. These functions are crucial for the maintenance of male characteristics, but also for the preservation of species, which will be further described in this article. The mammalian testis is covered by a protective fibrous capsule, the tunica albuginea, composed mainly of collagen with some fibroblastic and smooth muscle elements. The thickness, composition and amount of connective tissue shows tremendous variation among species and its percentage in the testis ranges from ~4% in mice to ~20% in humans. The capsule extends from the tunica inward, forming the testicular parenchyma, but also delineates the rete testis and the mediastinum. Besides its protective function, this capsule is also involved in regulating blood flow, temperature, pressure and sperm movement (Russell and França, 1995).

Functionally, the testis parenchyma is organized into two major compartments: tubular and intertubular, also called the interstitium (Fig. 1). The tubular compartment is composed by seminiferous tubules that can be subdivided from its exterior wall to its center into tunica propria, seminiferous epithelium and tubular lumen. The tunica propria contains the peritubular smooth muscle-like myoid cells, that form one (ex: mice and rat) to several layers (ex: humans and marsupials) according to the species, containing also collagen and laminin fibers. The seminiferous epithelium is a highly organized tubular lining that is integrated with germ cells and the somatic, supporting Sertoli cells, which also secrete the fluid responsible for tubular lumen formation and sperm transport. No blood vessels, nerves or other cell types are present in the seminiferous epithelium. The tubular diameter shows high variation among mammals (Table 1), ranging from ~160 to ~450 μm in mammals. In the intertubular compartment, the steroidogenic Leydig cells are usually the most frequent cell type present. Besides these cells, blood and lymphatic

Fig. 1 Testis parenchyma composition in adult mouse, depicting the two main compartments of the testis: tubular and intertubular. The tubular compartment is constituted by the tunica propria, constituted by peritubular myoid cells and basal lamina, and seminiferous epithelium, composed by Sertoli cells and germ cells in different stages of development, with a central tubular lumen. In the intertubular compartment, Leydig cells are found adjacent to blood vessels, lymphatic vessels (not shown) and fibers and cells of connective tissue (not shown).

vessels, nerves, mast cells, macrophage and dendritic cells, as well as fibroblasts and connective tissue fibers are found in the interstitium, and their amount varies significantly according to the species. Although spermatogenic and steroidogenic activities occur in two distinct functional compartments of the testis, their full accomplishments require very complex cellular and physiological interactions between both, an important aspect that is advanced in other chapters.

As shown in **Table 1**, although the testis compartments are similarly organized among the mammalian species already investigated, high variation is noted for several representative parameters, such as the gonadosomatic index (testis mass/body mass), the percentage occupied by seminiferous tubules and Leydig cells in testicular parenchyma, tubular diameter, Leydig and Sertoli cell numbers, Sertoli cell efficiency and, as a consequence, spermatogenic efficiency (daily sperm production per testis gram). For instance, human spermatogenic efficiency is very low, particularly when compared to rodents. Large variation is also observed for the percentage of Leydig cells, ranging from ~1% in *Akodon montensis* to ~30% in capybara, the biggest rodent worldwide, with a predominant investment in male dominance through androgens, instead of sperm production.

Fig. 2 illustrates testis histology in some mammalian species depicted in **Table 1**. In this figure, it is easy to recognize the large area occupied by connective tissue within the intertubular compartment in human testis, whereas the percentage of interstitial space taken by Leydig cells in capybaras can reach up to 80% in some males. In the collared peccary, these steroidogenic cells present a unique and peculiar arrangement in the testis parenchyma, forming dark stripes around the seminiferous tubules lobes, due to the high lipid content in the cytoplasm of these cells. It is considered that these functional differences among species are related, for instance, to their reproductive strategies. Besides that, the knowledge of these peculiar characteristics makes a given species an interesting model for the investigation of testis function. For example, studies were developed in our laboratory using the collared peccary to evaluate Leydig cell influence on the spermatogonial niche and spermatogonial differentiation (Campos-Junior et al., 2012), an aspect that will be presented in more detail in the last section of this book chapter.

Spermatogenesis

Spermatogenesis is a highly organized process that occurs in the seminiferous epithelium and is orchestrated by Sertoli cells. Based mainly on morphological and functional criteria, this process has been classically divided into three well-characterized phases, named spermatogonial (proliferative), spermatocytary (meiotic) and spermiogenic (differentiation). However, due to several recent findings related to spermatogonial stem cell biology and regulation, the spermatogonial phase could be subdivided into two functionally different categories or subsets, comprising the undifferentiated and differentiated spermatogonial pools (**Fig. 3**). Germ cells are not randomly distributed in the seminiferous epithelium, but organized in distinct and regular cellular associations known as stages of the seminiferous epithelial cycle (Hess and França, 2007). In this article, the germ cell types as well as spermatogenic phases and the basic Sertoli cell functions will be briefly described.

Germ Cell Syncytium and Apoptosis

Incomplete cytokinesis during mitosis is a typical feature of germ cells and spermatogenesis. This morphofunctional phenomenon forms an intercellular communication by creating stable intercellular bridges, also called cytoplasmic bridges, which are

Fig. 2 Comparative testis histology of four representative mammalian species: *Akodon montensis*, capybara, collared peccary and human. Observe the differences in volume density of the two testis compartments—the seminiferous tubules (ST) and intertubular compartments (IC). Leydig cell volume density (%) is much higher in capybara, whereas very few Leydig cells are observed in the wild rodent *Akodon montensis*. In the peccary, these steroidogenic cells present a unique and peculiar arrangement in the testis parenchyma, forming dark stripes around the seminiferous tubules lobes, due to the high lipid content in their cytoplasm (insert). In man, connective tissue of the intertubular compartment is quite extensive.

maintained throughout spermatogenesis. The intercellular bridge is large enough to allow the passage and sharing of cell organelles, such as mitochondria, and several molecular signals. The type A single (As) spermatogonium is considered the only dividing germ cell without intercellular bridges. It was shown that *Tex14* knockout mice present defects in the intercellular bridges formation and, consequently, the germ cells were unable to complete meiosis, making these rodents infertile. As reviewed by [Greenbaum et al. \(2011\)](#), several roles for mammalian intercellular bridges in spermatogenesis have been proposed, including the following:

- sharing products of both sexual chromosomes, so haploid cells can remain “phenotypically diploid” even after meiosis;
- allowing the transference of cytoplasmic signals, important to maintain the synchrony in cell divisions; and
- producing a uniform population of sperm, detecting possible errors during germ cell development and facilitating the elimination of the entire syncytium by apoptosis.

Germ cell loss is normally observed in the adult testis, contributing therefore to the maintenance of healthy spermatogenesis and determining the total sperm output. Thus, an intricate homeostatic control of germ cell renewal, proliferation and apoptosis is necessary to maintain normal sperm production. In this regard, significant germ cell loss occurs during the spermatogonial phase, mainly regulating the density of these cells, which possibly represents an early mechanism to limit the number of germ cells that can be supported by each Sertoli cell. Apoptosis is also frequently observed during meiosis, probably serving as a defense mechanism for the preservation of the species and as quality control for monitoring chromosomal damage in the spermatocytes. The extent and purpose of spermatid apoptosis is less clear, but may also be associated with quality control, especially as related to DNA integrity after chromatin condensation ([Fig. 4](#)) ([Murphy and Richburg, 2014](#)), or represent a mechanism related to the finite number of germ cells that each individual Sertoli cell is capable of supporting. The rate of apoptosis, the most affected cell types affected, as well as the pathways involved in this process vary significantly among species.

Fig. 3 Schematic representation of the mouse spermatogenic process: spermatogonial, meiotic and spermiogenic phases. Spermatogonial phase can be subdivided into two distinct functional categories, that is, undifferentiated and differentiated spermatogonia. The type A single spermatogonium (As) is considered the true stem cell, while type A paired (Apr) and A aligned (Aal₄₋₁₆) are considered amplifying stem cells. There is a fine balance between differentiation and self-renewal in the undifferentiated spermatogonial pool before the final differentiation (*dotted green line*) to type A1 spermatogonium (A1). After that, these cells are considered definitively committed to sperm production, going through meiotic and spermiogenic phases. Spermatogonial cells: type A undifferentiated [single (As), paired (Apr) and aligned (Aal₄₋₁₆)] and differentiated (A1–4); intermediate (In); and type B (B) spermatogonia. Primary spermatocytes: preleptotene (Pl), leptotene (L), zygotene (Z), pachytene (P) and diplotene (D) spermatocytes. Meiotic divisions (MI and MII). Secondary spermatocyte (II). Round (R) and elongated spermatids (E).

Fig. 4 Schematic illustration of germ cell loss (*red*) during spermatogenesis and the potential reasons for apoptosis of these cells in each phase of the spermatogenic process.

Spermatogonial Phase

Undifferentiated spermatogonia

This category or subset, as mentioned above, is responsible for maintaining the balance between self-renewal and differentiation, which is fundamental for ensuring continuous sperm production in mammals. This category is comprised of single (As), paired (Apr) and aligned (Aal) type A spermatogonia. In the past, single spermatogonia were considered the true stem cell among germ cells. However, because Apr and Aal spermatogonia have the ability to return to a more undifferentiated state through

syncytial/clonal fragmentation in a steady state, several recent studies have demonstrated that these cells are considered as both progenitors and amplifying cells of the spermatogenic process. This characteristic is very important in regulating the number of cells that can progress and be sustained throughout the next steps of spermatogenesis. These undifferentiated cells are normally present in all stages of the seminiferous epithelial cycle and the size of the syncytium/clones (Apr, Aal 4, 8, 16) in mice determines the type and prevalence of the membrane receptors involved in self-renewal and/or differentiation (Yoshida, 2012).

Several studies, mainly in mice, have shown that As and Apr spermatogonia present higher expressions of GFRA1 (GDNF family receptor alpha-1) and Nanos2 (Nanos homolog 2), which are factors involved in self-renewal. As soon as these cells start to differentiate and become Aal spermatogonia (Al 4, 8, 16), a gradual reduction of these factors is observed, while the expression of Neurogenin-3 and RAR (retinoic acid receptor) increases, concomitantly with the spermatogonial syncytium/clones enlargement. Lower expression of RAR on As and Apr spermatogonia ensures that these cells do not differentiate at the stages nearing spermiation, when the levels of retinoic acid (which stimulates germ cell differentiation) are elevated. This control prevents the depletion of spermatogonial stocks for the next cycle, ensuring continuous sperm production. Aal spermatogonia normally express the RAR and receive retinoic acid stimuli, which starts the expression of a classic stem cell factor receptor, known as c-kit, and is considered crucial for spermatogonial proliferation and differentiation (Fig. 5).

Differentiated spermatogonia

This category of spermatogonia is observed after the differentiation of As, Apr or Aal spermatogonial types, under retinoic acid influence. Because the newly formed cells are committed to sperm production, losing their reversibility characteristic is a functional process crucial for spermatogenesis. The differentiation process occurs concomitantly with spermiation and type B spermatogonia division to preleptotene spermatocytes, and this germ cell composition in the seminiferous epithelium determines the quantity of retinoic acid available to promote spermatogonial differentiation. After differentiation, spermatogonia pass through successive mitotic divisions until the formation of preleptotene cells. The number of mitotic divisions is related to the number of differentiated spermatogonial generations in a species, which seems to be phylogenetically determined and highly correlated with the magnitude of sperm production. For example, due to the fact that most rodents present five more generations of differentiated spermatogonia than humans, the expected number of sperm produced could be up to 32-fold higher (Fig. 6). In contrast to the previous subset (undifferentiated spermatogonia), the presence of differentiated spermatogonia occurs in specific germ cell associations, called stages of the seminiferous epithelial cycle, which presents germ cells at different states of differentiation (please see below) (Hess, 1990; Hess and França, 2007). It is worth mentioning that the characterization of differentiated spermatogonial cell types is based on the presence of heterochromatin, whereas their generation number is based on the presence of mitotic figures and the quantification of spermatogonial cells per seminiferous tubule cross-section.

Meiotic Phase

Similar to the transition of undifferentiated to differentiated spermatogonia, due to the capacity of type B spermatogonia to express retinoic acid receptors and yield preleptotene spermatocytes, the transition from mitosis to meiosis also depends of retinoic acid. Thus, *Stra8* (stimulated by retinoic acid gene 8) is activated after the direct action of retinoic acid in the spermatogonium and triggers the expression of important transcription factors, assuring DNA replication and the subsequent events of meiotic prophase.

During meiosis, pairing, synapsis, crossing-over and segregation of homologous chromosomes are observed. This complex and crucial process starts with the division of the type B spermatogonia, generating preleptotene spermatocytes (Pl) (Fig. 7). Pl are the first meiotic cells to be formed and are actively involved in DNA synthesis, being usually the last germ cells to synthesize this molecule. Pl are followed by leptotene spermatocytes, when the chromosomes become more apparent as long strands and form a peculiar arrangement called bouquet. Chromosomal pairing and synaptonemal complex formation start in zygotene and are

Fig. 5 Molecular expressions that are characteristic of undifferentiated and differentiated spermatogonial cells. Single (As) and paired (Apr) spermatogonia express high levels of self-renewal factors (GFRA1 and Nanos2), while aligned (Aal₄₋₁₆) spermatogonia show higher expression of proteins involved in differentiation (RAR-Y and Neurog3). After differentiation, the type A1, A2, A3, A4, Intermediate (In) and B spermatogonia predominantly express a protein (c-kit) involved in germ cell proliferation and differentiation.

Fig. 6 Number of differentiated spermatogonia generations and the magnitude of sperm production. Contrasting with the number of cellular divisions (two) that are constant during meiosis, the number of differentiated spermatogonial generations, which seems to be considered phylogenetically determined, significantly varies among the mammalian species; directly influencing therefore the magnitude of sperm production. Spermatogonial phase: type A (A1–4); intermediate (In); and type B (B) spermatogonia. Meiotic phase: preleptotene (P1), leptotene (L), zygotene (Z), pachytene (P) and diplotene (D) spermatocytes; meiotic divisions (M1 and M2); secondary spermatocyte (S2). Spermiogenic phase: Round (R) and elongated spermatids (E). The number present in the tip of the bar represents the possible number of cells yield, whereas $\times 2$ illustrates the cell divisions after the differentiated spermatogonial phase.

completed in pachytene spermatocytes. In this last step, thickening and shortening of the chromosomes and exchange of chromosomal material occur, in a process called crossing-over, which is responsible for genetic variability among individuals within the same species. The end of synaptonemal complex occurs in the diplotene spermatocyte, when the chromosomes are partially separated. Diakinesis involves the separation of chromosomes into two sister chromatids. This first meiotic prophase is followed by metaphase, when the paired chromatids concentrate at the equator of the germ cell. Anaphase involves the movement of paired chromatids towards the cell poles, and telophase gives rise to daughter cells called secondary spermatocytes. Different from primary spermatocytes, these cells have a very short life span, with haploid number of chromosomes, although they have duplicated DNA content. The secondary spermatocytes pass through the second meiotic division very quickly, forming the round spermatids, which present a haploid content of chromosomal DNA (Fig. 7).

Spermiogenic Phase

The spermiogenic phase is a long process in which haploid, round spermatids pass through striking morphological changes until spermatozoa formation. The structural and functional changes that occur in the developing spermatids are usually subdivided into steps. During this phase, the following cellular events can be observed: (a) formation of new organelles, including the chromatoid body composed by RNA; (b) nuclear chromatin compaction; (c) acrosome formation by the Golgi apparatus; (d) flagellum formation; (e) development of ectoplasmic specializations and tubulobulbar complexes at the interface between Sertoli cells and elongating/elongated spermatids; (f) elimination of cytoplasm by spermatids (residual body); and (g) release of spermatids from the seminiferous epithelium (spermiation). Therefore, during spermiogenesis, many important genes/proteins have specific and crucial roles in the development of spermatozoa.

This spermatogenic phase is highly dependent on androgens (steroids) and the presence of androgen binding proteins (ABP) located in the Sertoli cell processes promotes high androgen concentrations near the elongated spermatids. Through the maintenance of spermatid adhesions to Sertoli cells, androgens induce elongation of the final steps of spermatids. Furthermore, several studies have demonstrated that testosterone is able to sustain complete spermatid differentiation by itself. In addition, follicle-stimulating hormone (FSH) has also an important role in sperm cytostructural modifications, acting on round spermatid flagellum extrusion and in the replacement of histones by protamines during spermiogenesis, assuring therefore the correct condensation of spermatid nuclei (Smith and Walker, 2014). Recent studies have also shown estrogen pathways to be involved in the preparation of elongating spermatids for release during spermiation (Kumar et al., 2017).

Sertoli Cell

Sertoli cells orchestrate germ cells development and differentiation, being therefore crucial for the completion of spermatogenesis. Among the innumerable Sertoli cells functions the following should be mentioned: (a) delivery of nutrients and growth factors for spermatogenic cells; (b) physical support of germ cells; (c) release of the spermatids towards the tubular lumen during spermiation;

Fig. 7 Morphology and characterization of mouse spermatocytes at different stages of the meiotic phase of spermatogenesis. During meiosis, pairing, synapsis, crossing-over and segregation of homologues chromosomes are observed. The main characteristics/events presented in each cellular phases or steps (preleptotene, leptotene, zygotene, pachytene, diplotene, meiosis I, secondary spermatocytes, meiosis II and spermatids) are listed in the boxes placed below each considered spermatocyte type.

(d) secretion of tubular fluid; (e) phagocytosis of cytoplasm (the residual body) derived from late spermatids; and (f) phagocytosis of apoptotic germ cells. In addition, due to the presence of FSH, androgens, estrogens and thyroid hormones receptors, Sertoli cells also intermediate most of the hormonal regulation of spermatogenesis (Fig. 8A). Sertoli cells are able to accomplish these numerous, and sometimes simultaneous, functions because each cell is tall and extends through the entire height of the epithelium, from basement membrane to the lumen (Hess and Vogl, 2015). Cytoplasmic arms of each Sertoli cell is capable of extending around four different generations of developing germ cells, as it forms intricate membrane organelles. Its surface area can reach $16,000 \mu\text{m}^2$. Sertoli cells change dramatically in morphology and physiology over the course of the seminiferous epithelial cycle, with the translocation of numerous organelles, expression of numerous different proteins for specific functions, and changes in the location of these proteins to meet different needs of the changing germ cell associations.

In mammals, Sertoli cells are known to proliferate actively during the fetal period, presenting, at least in well-investigated laboratory rodents (mice and rats), a peak in proliferation just before birth. Postnatally, its proliferation extends for around 2–3 weeks

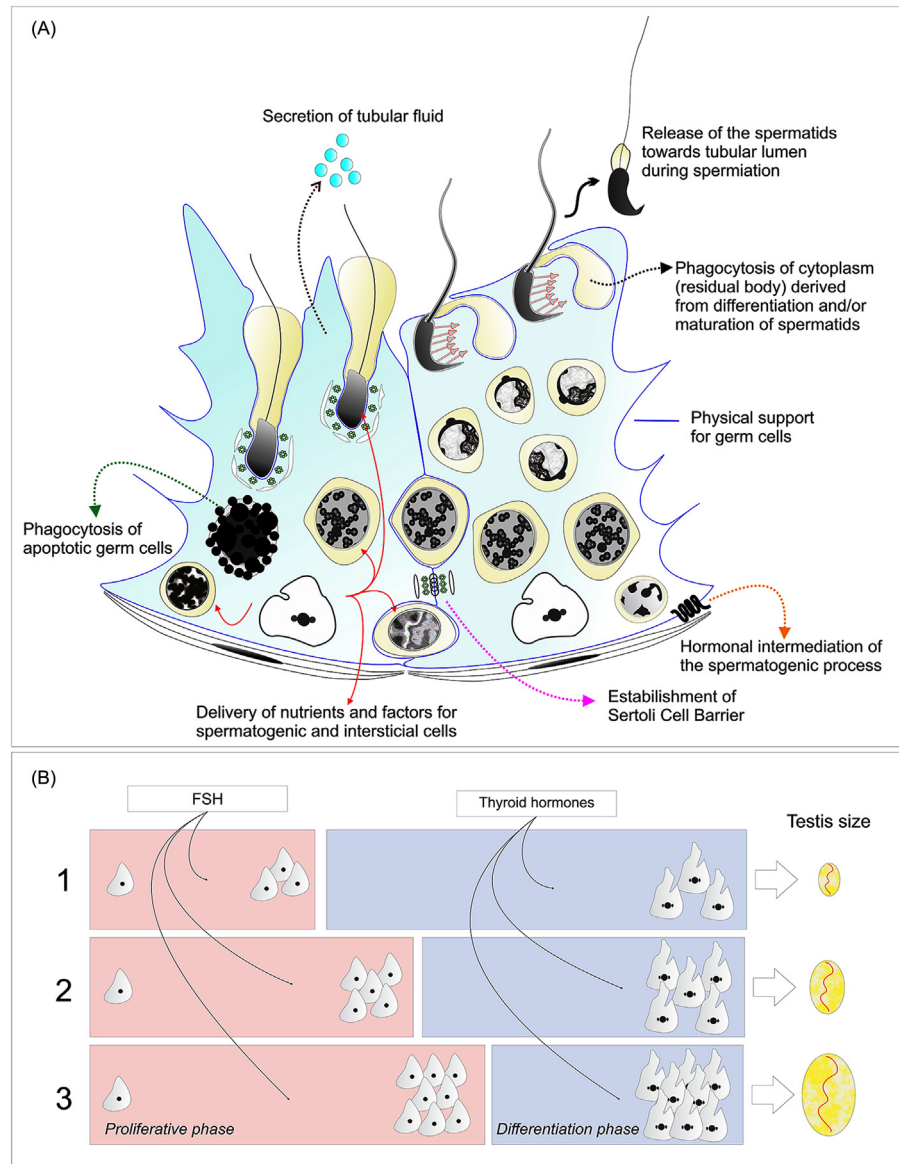

Fig. 8 Main Sertoli cell functions and the balance between Sertoli cell proliferation and differentiation. (A) Schematic illustration of the key factors related to the Sertoli cell functions. As it can be observed, the Sertoli cell is involved in crucial spermatogenic events, such as germ cell nutrition and support, signaling, hormonal intermediation, luminal fluid secretion, endocytosis and spermiation. (B) Length of the Sertoli cell proliferation window (pink boxes) is crucial to the determination of their final number. The major factors controlling proliferation and differentiation phases of Sertoli cells are FSH and thyroid hormones, respectively. In laboratory rodents, experimental manipulation of these factors can shorten (B1) or prolong (B3) Sertoli cell proliferation, resulting respectively in smaller and larger testis/sperm production. (B2) Animals under normal conditions, exhibit an equilibrium between proliferative and differentiation phases.

after birth in rats and 10–15 days in mice, and the end of its mitotic phase is correlated with the initiation of primary spermatocyte differentiation, Sertoli cell-barrier development and fluid secretion/lumen formation. In humans, Sertoli cells proliferate during the perinatal and neonatal periods, and it is believed that this somatic cell becomes quiescent for several years, followed by a second proliferation peak in response to increased gonadotrophins at puberty. A similar pattern is observed in pigs, but the second proliferation peak occurs in a matter of months and not years, because puberty in pigs occurs around 4 months of age. Except for the transitional area between the seminiferous tubules and the *rete testis*, in adulthood the number of Sertoli cells in the testis is rather stable. However, recent *in vitro* and *in vivo* studies, in laboratory animals, seasonal animals (hamsters) and humans, suggest that there is a fine modulation of Sertoli cell differentiation. Therefore, these cells seem to be able to return to a more immature state or, additionally, a specific population of Sertoli cells can keep their immature/stemness state, which could be the situation for Sertoli cells located in the transitional area between seminiferous tubules and the *rete testis* (Figueiredo et al., 2016).

Although the mechanisms that regulate Sertoli cell proliferation are not yet completely elucidated, it is strongly suggested that FSH is the main factor involved in this process. However, other factors such as for instance androgens, estrogens, activin, TGF- β , BMP2, BMP7, IL1 and TNF α , probably play important roles on Sertoli cell proliferation. In contrast to FSH, thyroid hormones are responsible for the differentiation/maturation of Sertoli cells, changing them functionally from a mitotic to a non-mitotic state. As each Sertoli cell is capable of supporting a relatively fixed number of germ cells, in a species-specific manner, experimental manipulation of the Sertoli cell population will affect the spermatogonial niche functionality and, ultimately, the magnitude of sperm production (Fig. 8B–D).

As already mentioned, the stabilization of Sertoli cell proliferation and their functional maturation coincide with the development of the blood–testis or Sertoli cell-barrier (SCB). The anatomical basis of SCB consists of the establishment of tight junctions between Sertoli cells, in addition to the presence of basal ectoplasmic specializations, gap and adherens junctional proteins, which also contribute to this structural and functional junctional complex. Therefore, at the molecular level, the SCB provides a physical barrier to segregate the cellular events of spermatogenesis, particularly controlling and restricting the paracellular transport of several substances (paracrine factors, hormones and biological molecules) across the seminiferous epithelium. Additionally, the SCB also helps to establish an immunoprivileged microenvironment for the development of the spermatogenic process, which is especially important as meiotic germ cells and developing spermatids can produce several immunogenic autoantigens. Furthermore, studies have shown that the SCB is also involved in different cellular events during spermatogenesis; for example, spermatogonial differentiation, initiation of meiosis, or reinitiation of spermatogenesis after a toxic injury (França et al., 2016).

Stages and Cycle of the Seminiferous Epithelium and Spermatogenic Wave

Stage classification methods are very useful and enable studies involving toxicological and comparative analyses, making it possible to follow specific cellular alterations caused by the administration of drugs that promote changes in spermatogenesis. In a tubular cross-section, it is observed that the seminiferous epithelium is composed of Sertoli and germ cells that are closely associated. It can also be noted that, differing from Sertoli cells, germ cells are organized in a well-defined manner in concentric layers, where the most immature germ cells (spermatogonia and early spermatocytes) are located at the base of the seminiferous epithelium, adjacent to the basement membrane, while more advanced germ cells (leptotene/zygotene to spermatids) occupy successive layers towards the tubular lumen.

In 1952, Leblond and Clermont described a classical method in which they accurately defined the germ cell associations present in seminiferous tubules of rats and found that these associations, although different, were constant and with a specific time duration. Analyzing the development of the spermatid acrosomal system, these scientists classified rat spermatogenesis into 14 cellular associations, called stages. In rodents and most non-primate species, one stage occupies a cross section of a seminiferous tubule. Based on the same methodology, 12 different stages were described in mice (Fig. 9) and 6 in man. At the same time, another method for stage classification, named the tubular morphology system, was already described. In the tubular method, only eight stages of the seminiferous epithelium cycle are described for any species evaluated, but these stages include all cells and steps seen with the acrosomal system of classification. This latter classification, used for several mammalian species, takes into account the spermatid nuclear morphology and localization, their association with other germ cell types (i.e., differentiated spermatogonia and spermatocytes) and the presence of meiotic figures. More recently, another classification that could integrate both acrosomal and tubular morphology systems was developed. In this simpler and useful classification, the spermatogenic process was divided into six representative phases: (I) before meiosis; (II) after meiosis; (III) presence of acrosomal granule; (IV) presence of acrosome; (V) pre-spermiation; and (VI) post-spermiation. A novel immunohistochemical approach was also recently introduced, in which the stages are visualized using immunolocalization of proteins that identify specific germ cells and Sertoli cells and label the acrosomal formation (Nakata et al., 2015). As more and more antibodies become available, this latter method of classification may become more popular, as it provides a powerful method for tracing gene/protein expressions through the cycle of spermatogenesis. Independent of the classification criteria used, in humans and some other primate species more than one stage is observed per cross section of the seminiferous tubule. The functional meaning for this finding is still unknown but might be related to the germ cell clonal size, an aspect that surely deserves an accurate investigation.

Development of the stages is not related to any movement in the longitudinal axis of the seminiferous tubule. However, there is a distinct order of cellular associations (stages) along the length of the tubule, forming linear segments. The continuity of these segments is usually observed in a descending sequence from the proximal connections to the *rete testis* to the approximate center of the tubule, where the stage sequence is reversed (Nakata et al., 2017); thus, stage VII would be adjacent to stage VI, and so on. This

Fig. 9 Stages I–XII of the seminiferous epithelial cycle in the mouse, according to the development of the acrosomic system. The individual germ cell nuclei shown in the right column represent the germ cells found in association at each particular stage. A, type A differentiated spermatogonia; In, intermediate spermatogonia; B, type B spermatogonia; PL, preleptotene; L, leptotene; Z, zygotene; P, pachytene; D, diplotene spermatocytes; meiosis, meiotic figure; S2, secondary spermatocyte; R, round spermatids; E, elongating/elongated spermatids; SC, Sertoli cells.

special arrangement will eventually lead to a complete series of stages, defined as a spermatogenic wave. However, unfortunately, very few species were investigated in this particular aspect, making the spermatogenic wave still a not very well understood functional aspect of spermatogenesis. Nevertheless, it is considered that the importance of wave is a continuous commitment of germ cells to the cycle, as well as the release of sperm along the seminiferous tubules in a steady way in non-seasonal breeders, ensuring therefore constant sperm production and maturation (Griswold, 2016).

In association with the concept of spermatogenic phases, the cycle of the seminiferous epithelium was defined as a series of transformations that occur, within the same stage, leading to the differentiation of germ cells in a vertical way. It means that one cycle can be represented by the differentiation of spermatogonia into spermatocytes and spermatocytes into spermatids at the same stage. Thus, the cycle of the seminiferous epithelium was characterized as a temporal and sequential event (time and space) of changes in cellular associations in a given area of the seminiferous tubule. Several studies have suggested that Sertoli cells cyclically change their functions, coordinating the differentiation of germ cells. One of the most important candidates to play a role in this regulation is the retinoic acid, which acts as a stimulator of the periodic germ cells differentiation. For instance, it was shown that an increase in retinoic acid signaling is able to induce type A spermatogonia differentiation and influence Sertoli cell gene expression, modulating their action on the other germ cells (Hess and França, 2007; Griswold, 2016).

Another very important functional aspect of spermatogenesis is duration of the seminiferous epithelium cycle. Although controlled by the germ cell genotype (França et al., 1998), it is considered species-specific and does not have a conserved feature among species or orders. Nevertheless, several studies, mainly from our research group, have demonstrated that phylogeny is usually associated with stage frequencies, particularly when considering the combination of stages in pre-meiotic and post-meiotic phases among closely related species. Therefore, when the frequencies of these two combined phases are considered, three patterns can be recognized among species: (1) a relative equilibrium between pre-meiotic and post-meiotic phase frequencies (e.g., marsupials); (2) pre-meiotic phase corresponding to two thirds of the spermatogenic cycle (e.g., ruminants); and (3) pre-meiotic

Table 2 Frequencies of pre-meiotic, meiotic and post-meiotic stages of the seminiferous epithelium cycle and the duration of each spermatogenic cycle and the total spermatogenesis in several mammalian species

	Pre-meiotic (%) ^a	Meiotic (%) ^b	Post-meiotic (%) ^c	Spermatogenic cycle length (days)	Total duration of spermatogenesis (days)
Mouse	18–23	9–11	66–71	8.6–8.9	38.7–40.1
Rat	24	5	71	12.9	58
Hamster	26–29	5.5–7.5	65–66	9–17	39–76
<i>Akodon montensis</i>	28	8.2	63.8	8.9	40
Capybara	44.8	14.6	40.6	11.9	53.5
Collared peccary	38	11	51	12.6	55.1
Boar	28–31	12	56–60	9	40.5
Opossum	48.9	4.8	46.3	17.3	77.9
Cat	45.5	17.6	36.9	10.4	46.8
Dog	37–41	7–11	50–57	12.6–13.8	56–62
Horse	35	15.8	49.2	12.2	54.9
Bovine	64.7	8.8	26.5	14	63
Buffalo	64.8	9.2	26.0	8.6	38.7
Goat	58.7	9.4	31.9	10.6	47.7
Marmoset	61	8	31	15.4	69.1
Human	45–75	5–7	20–50	16	72

frequency lasting about one-quarter of the entire spermatogenic cycle (e.g., laboratory rodents) (Table 2). As also observed in Table 2, in most mammalian species investigated up-to-date the total duration of spermatogenesis is situated in the range of ~40 to ~60 days. It means that, from undifferentiated spermatogonia, usually less than 2 months are required for the formation and release (spermiation) of sperm from the seminiferous epithelium.

Leydig Cells and Steroidogenesis

As previously noted in Table 1, the steroidogenic Leydig cell is the most frequent cell type observed in the intertubular compartment. The Leydig cell exhibits huge variations in individual volumes among mammalian species. For instance, in humans and horses the Leydig cell individual volume reaches more than 4000 μm^3 , whereas in *Akodon montensis* this value is around 800 μm^3 , being only 400 μm^3 in rams. Interestingly, in a comparative study not yet published from our laboratory, involving 10 different breeds of dogs, we observed that the more aggressive breeds (pitbull and pincher) have a much greater occupancy of Leydig cells, compared to other breeds such as the poodle, whose testis has a much larger tubular compartment and spermatogenic efficiency. These findings illustrate the importance of evaluating the testis compartments, in order to have a better understanding of reproductive strategies and animal behavior.

The pattern of distribution and organization (cytoarchitecture) of Leydig cells in the intertubular compartment is highly variable among the mammals species already investigated (see Fig. 2) and probably represents important functional aspects that are yet unknown or have not been clearly elucidated. The last comprehensive review of this subject was published more than four decades ago (Fawcett et al., 1973). A recent publication from our laboratory showed that in the collared peccary Leydig cells present a unique cytoarchitecture, forming a cord-like structure surrounding the seminiferous tubules lobes, and only very few Leydig cells are present among the seminiferous tubules. This pattern markedly differs from those already described by Fawcett and colleagues in 1973. Taking advantage of this knowledge, we developed studies regarding spermatogonial stem cell biology and niche in this species, in which we found that, in contrast to differentiated type A spermatogonia, the undifferentiated spermatogonial cells were located closer to the intertubular compartment areas without Leydig cells (Campos-Junior et al., 2012). In another investigation, we observed that, during postnatal testis development in pigs, and somewhat similar to horses, seminiferous tubule maturation and lumen formation follow an asymmetric pattern, being more advanced in the intermediate areas distant from the tunica albuginea and closer to the central area, where the rete testis and the testis mediastinum are located (Avelar et al., 2010). Interestingly, individual Leydig cell volume in the intermediate areas was always much larger at all investigated ages, maintaining this functional pattern even in sexually mature pigs. As similar results are now being observed for the seminiferous tubules in rodents, having the rete testis as a reference point, these striking finding open new venues for testis function investigation and, once more, reinforces the functional interactions between the two different testis compartments.

Regarding androgen production in the testis, it has been suggested that testosterone levels are more related to mitochondria and smooth endoplasmic reticulum present in the cytoplasm than in the Leydig cells number and size. In addition, in comparison to the plasma levels, intratesticular testosterone concentration is strikingly higher, meaning that normal spermatogenesis demands a rather high amount of androgens. As already mentioned, testis steroidogenesis is crucial for maintenance of androgen levels, being

essential for the completion of full spermatogenesis and for the development and preservation of sexual male characteristics. Overall, androgen controls spermatogenesis through Sertoli cell intermediation, as germ cells per se do not express receptors for these hormones. Androgens and probably other steroids, including estrogen, are especially necessary for spermiogenesis and sperm release.

The production of androgens and steroids in general begins as early as gonadal differentiation takes place and it is maintained up to senescence, when its levels decrease. In this context, it has been demonstrated that Leydig cell capacity for producing testosterone varies along with the different phases of testis development and is associated with the enzymatic composition of these cells. Hence, studies in the literature reported that during fetal life a particular Leydig cell population is present in the testis, producing androgen as an intermediate product. At this phase, it was recently shown that Sertoli cells are remarkably necessary for completion of testosterone synthesis, once these supporting somatic cells express 17 β -hydroxysteroid dehydrogenase 3 (*Hsd17b3*), the last enzymatic step necessary for testosterone production. *Hsd17b3* is not detected in Fetal Leydig cells. Thus, the androgen produced by Fetal Leydig cell is delivered to the Sertoli cell that will provide the final conversion to testosterone (Shima and Morohashi, 2017). Postnatally, the Leydig cell population changes dramatically and the Adult type Leydig cell develops the enzymatic machinery necessary to accomplish testosterone production. Concomitantly, *Hsd17b3* gene is silenced in Sertoli cells and, in this respect, the only source of testosterone in post pubertal testis is the Leydig cell (Ye et al., 2017). In this context, the rather substantial interactions between Leydig cells and macrophages and the possibility of the coexistence of distinct Leydig cells populations in the testis of some species represent an interesting aspect of testis function that might be taken into consideration in future studies.

Spermatogonial Stem Cell and Niche

Introduction

Spermatogonial stem cells (SSCs) are the cornerstone of the entire male germ cell lineage in postnatal life. Indeed, the billions of sperm produced throughout the reproductive lifespan of a male are derived from a pool of SSCs. Continuous spermatogenesis, therefore, requires a robust SSC pool that not only self-renews to maintain the stem cell pool, but also generates large numbers of progenitors that will ultimately form spermatozoa. Thus, complex regulatory systems delicately balance fate decisions of SSCs between self-renewal and progenitor formation, which are thought to be driven by factors from a specified microenvironment, also known as the *niche*. Somatic cells, systemic circulation, and other germ cells are thought to all contribute to niche composition and ultimately communicate with SSCs to maintain continuous spermatogenesis. In this article, we will briefly discuss the current breadth of knowledge in SSC niche composition and the known factors that regulate SCC function.

The Stem Cell Niche

The term *niche* was first coined by Schofield in 1978 to describe a specialized anatomical microenvironment that controls stem cell dynamics and function (Schofield, 1978). In general, niches are regulatory units that control the capacity of tissue-specific stem cells to either self-renew or produce progenitors through cell division. Tissue-specific stem cells are thought to divide by one of three modes: (1) symmetrical division generating two identical stem cells, (2) symmetrical division producing two progenitors, or (3) asymmetrical division yielding one stem cell and one committed progenitor. SSCs are thought to divide either symmetrically forming two identical SSCs or asymmetrically to form an SSC and a progenitor; although this model has only been observed in *Drosophila melanogaster* (Tulina and Matunis, 2001) and *Caenorhabditis elegans* (Kimble and White, 1981), it remains to be determined in mammals. Regardless, dynamic changes in the SSC niche microenvironment control the fate decisions of SSCs toward either self-renewal or progenitor formation.

Stem cell niches are primarily comprised of a growth factor milieu, extracellular matrix elements, and other contributions from somatic support cells. Importantly, the composition of a stem cell niche is not static. For example, niches change during the course of development. As a stem cell lineage is establishing, niche composition drives fate decisions of stem cells that typically favor symmetrical division and self-renewal as the pool grows. Once steady-state conditions are reached, stem cells are thought to rarely self-renew and instead, periodically give rise to progenitors that amplify in numbers to populate a tissue and maintain homeostasis. In times of stress and regeneration, the stem cell niche also changes to support rebuilding of the cell lineage. Thus, there is plasticity in the niche environment based on the demands of the stem cell pool. In studies with mice, Shinohara et al. showed that SSCs derived from pups or adults have relatively equal stem cell capacity when transplanted into adult recipients, but colonization occurs 9.4 times more often and more expansively in recipient pups versus adults (Shinohara et al., 2001). These data suggest that although SSCs derived from pups or adults have similar stem cell capacity, the niche in pups is drastically different from adults and likely reflects remodeling that occurs over time as steady-state spermatogenesis is reached.

A_{single} Model

Classic morphological studies conducted by Huckins, Oakberg, and de Rooij in the 1970s utilizing rodent models paved the way for much of what we understand regarding the male germ cell lineage. In rodents, SSCs reside within a heterogeneous population of spermatogonia, composed of type A, Intermediate, and type B spermatogonia. The type A spermatogonia can be further divided into undifferentiated and differentiating subpopulations. SSCs are a rare subset of undifferentiated spermatogonia, with the remaining undifferentiated population being nonstem cell progenitors. In the prevailing “A_{single}” model of spermatogonial differentiation, SSCs are thought to predominantly exist as single type A undifferentiated spermatogonia (A_{single} or A_s). Recent studies suggest that the A_s population is a heterogeneous pool composed of both true SSCs and SSCs transitioning to a nonstem cell progenitor phenotype (Lord and Oatley, 2017; de Rooij, 2017). Progenitors form paired (A_{paired} or A_{pr}) and aligned (A_{aligned} or A_{al}) chains of 2–32 undifferentiated spermatogonia persistently connected by intracellular bridges formed after incomplete cytokinesis. These intracellular bridges facilitate transfer of protein and mRNA between the progenitor spermatogonia and are thought to synchronize the process of differentiation. Retinoic acid (RA) triggers the terminal differentiation of A_{pr} and A_{al} undifferentiated spermatogonia which transition to an A1 differentiating state. A series of proliferation events lead to A2, A3, A4, Intermediate, and type B spermatogonia before meiosis initiates forming haploid spermatids and ultimately spermatozoa (Fig. 1).

In primates and humans, much less is known about the organization of the male germline. The undifferentiated population consists of two subtypes of A_s spermatogonia, A_{dark} (or A_d) and A_{pale} (or A_p), named for their differences in chromatin architecture and nuclear appearance through hematoxylin staining in histological studies. A_d spermatogonia are believed to constitute slow-cycling SSCs and A_p are the immediate nonstem cell progenitors that enter differentiation to form type B spermatogonia. However,

Fig. 1 Schematic of the “A_{single}” model of spermatogonial differentiation. The undifferentiated pool of spermatogonia consists of rare spermatogonial stem cells (SSCs) and type A undifferentiated progenitors arranged as single (A_s), paired (A_{pr}), or aligned chains (A_{al}) of spermatogonia. SSCs divide either symmetrically to self-renew or asymmetrically producing undifferentiated progenitors that transition to a differentiating phenotype in response to retinoic acid (RA). Differentiating spermatogonia proceed through a program of terminal differentiation to ultimately for spermatozoa.

it has been suggested that differences in nuclear morphology between A_d and A_p spermatogonia may simply be attributed to differences in cell cycle status among human and primate A_s spermatogonia (Hermann et al., 2009). Interestingly, human and primate spermatogonia lack intracellular bridges and upon induction of differentiation, transition directly to type B spermatogonia as opposed to type A differentiating and Intermediate spermatogonia as in rodents. Ultimately, these subtle differences in the organization of spermatogenesis between humans, primates, rodents, and other species is believed to underlie differences in total daily sperm output (Hermann et al., 2009).

Origin of the SSC Pool

Primordial germ cells (PGCs) are the earliest known embryonic precursors to the germ cell lineage for both males and females. PGCs arise from the proximal epiblast around embryonic day 6.5 (E6.5) in rodents and 2–3 weeks gestation in humans in response to bone morphogenetic proteins 4 and 8b (BMP4 and BMP8b) secreted by the extraembryonic ectoderm (Gunesdogan et al., 2014). PGCs then undergo a remarkable migration along the primitive hindgut to ultimately colonize the genital ridges adjacent the mesonephros, structures that will eventually form the gonads and kidneys, respectively. PGCs express C–X–C motif chemokine receptor 4 (CXCR4), a receptor that directs chemotactic migration toward the developing gonad via C–X–C chemokine motif ligand 12 (CXCL12) secreted from the genital ridges (Richardson and Lehmann, 2010). Likewise, the receptor c-Kit expressed by PGCs also participates in active migration—although more in the capacity of cell survival—in response to Kit ligand (Richardson and Lehmann, 2010). Thus, during the early stages of the SSC lineage, BMP4/8b, CXCL12, and Kit ligand are critical factors present in a dynamic niche environment.

While migrating to the genital ridges, PGCs rapidly proliferate and undergo genome-wide demethylation to prime the cells for later sex-specific remethylation. PGCs are initially bipotential, or capable for forming either male or female lineages. After colonizing the embryonic gonad, PGCs undergo sex determination and associate with somatic cells that regulate meiotic progression in a sex-specific manner. In females, PGCs form oogonia that enter meiosis in response to RA produced by the mesonephros. Oogonia then arrest in prophase I until shortly before ovulation in postnatal life. In males, PGCs transition to prospermatogonia but do not enter meiosis because associated Sertoli cells break down local RA via high levels of the RA-degrading enzyme Cyp26a1 (Koubova et al., 2006). Thus, RA is a critical niche component that regulates sex-specific meiotic progression of PGCs in the developing gonad.

Following sex determination, prospermatogonia begin reestablishing methylation imprints around E15 (in rodents) and proliferate until E16.5, at which point they enter a phase of mitotic arrest that persists until shortly after birth. Prospermatogonia inhabit the luminal cavity of seminiferous tubules (or seminiferous cords) during embryonic development. During the first

3 days of postnatal life, prospermatogonia migrate to the periphery of seminiferous tubules and colonize along the basement membrane adjacent Sertoli cells. Those prospermatogonia that colonize the basement membrane undergo a change in morphology and eventually re-enter the cell cycle around postnatal day 3. Prospermatogonia transition to SSCs during a defined window in postnatal development, which is believed to occur around postnatal day 6 in rodents and several months in primates and livestock.

Rodents are unique from higher order mammals such as primates and humans in that prospermatogonia that colonize the basement membrane become one of two different populations, either spermatogonia that directly enter differentiation to form the “first round of spermatogenesis” or SSCs that ultimately support subsequent rounds of spermatogenesis (Yoshida et al., 2006; Kluin and de Rooij, 1981). The first round of spermatogenesis in murine species is thought to have evolved from selective pressure to reach reproductive age faster; primates and humans lack this unique first round of sperm production. Otherwise, the sequence of events involved in the maturation of PGCs to SSCs appears to be conserved across most mammals, albeit with subtle differences in timing and/or duration.

SSC Homing and Transplantation

Homing is a term that describes the process by which stem cells migrate to and colonize niches. The ability of PGCs, prospermatogonia, or SSCs to home to a niche is essential for the establishment of continuous spermatogenesis and is also the basis for transplantation of SSCs into recipient testes. Tissue-specific stem cells, including SSCs, possess two definitive characteristics: (1) the ability to self-renew and maintain the entire cell lineage, and (2) the capacity to regenerate the cell lineage. Thus, transplantation is the most unequivocal measure of SSC content because transplanted cells must not only home to and colonize available niches, but also regenerate and sustain the spermatogenic lineage.

Transplantation of SSCs was first developed by Brinster and colleagues in 1994 (Oatley and Brinster, 2006; Brinster and Avarbock, 1994; Brinster and Zimmermann, 1994). The procedure involves dispensing cell suspensions containing SSCs through the efferent duct of recipient testes using a microinjection needle. The cell suspension fills the rete testis which feeds into the seminiferous lumen of each tubule. SSCs dispersed into the lumen migrate through the blood–testis barrier (BTB) to the basement membrane and occupy niches that will ultimately lead to repopulation of the testis, in a manner similar to what occurs during postnatal establishment of the SSC pool (discussed above). Transplantation efficiency is estimated to be between 5% and 12%, with niche availability and homing through the BTB being the limiting factors in SSC colonization.

From a research standpoint, transplantation is used as a functional assay to assess the stem cell capacity of the injected cell suspension (Helsel and Oatley, 2017). To evaluate only the experimental cell population, recipients are depleted of endogenous germ cells either experimentally using radiotherapy or various chemotherapeutics such as busulfan, or genetically where mice carry mutations in the c-Kit receptor (termed W/W^v). In the absence of a functional c-Kit receptor, PGCs do not colonize the gonad (discussed above) and thus produce mice devoid of a mature germline. Labeling of the injected cell population through the use of report transgenes such as *LacZ* or *Gfp*, enables quantification of donor-derived spermatogenic colonies. Each colony is derived from clonogenic expansion and differentiation from a single SSC (Dobrinski et al., 1999; Zhang et al., 2003; Kanatsu-Shinohara et al., 2006). Thus, one colony equates to one successful SSC transplanted. Therefore, transplantation can be used as a quantitative and qualitative measure of stem cell capacity. Lineage tracing is an experimental technique complimentary to transplantation for the qualitative assessment of stem cell potential, which involves marking stem cells with a constitutively-expressed reporter in such a way that all progeny derived from each stem cell will inherit the mark. Unfortunately, lineage tracing has limited quantitative value due to the limitations of chemically-driven labeling techniques (for more information, lineage tracing is reviewed in Kretzschmar and Watt, 2012). To date, transplantation is the most unequivocal functional measure of an SSC and a quantitative measure of SSC content from donor cell suspensions.

From a clinical standpoint, SSC transplantation offers a means of fertility restoration for men afflicted by certain types of infertility. Approximately 10% of couples are infertile worldwide, with half of all cases attributed to male factors (Chandra et al., 2013; Matzuk and Lamb, 2008). Impaired SSC function remains a leading cause of male infertility and transplantation could restore fertility in these men. Furthermore, SSCs are sensitive to radiotherapy and chemotherapeutic treatments (Holoch and Wald, 2011). While sperm cryopreservation overcomes the adverse effects of cancer therapies in adult men, prepubertal boys have yet to produce viable sperm and are thus susceptible to life-long infertility. Approximately 1 in 450 individuals are survivors of adolescent cancer, with both the incidence and survival of adolescent cancer continually rising (Gracia and Ginsberg, 2007). Thus, current research efforts are focusing on the isolation of SSCs and improving the efficiency of SSC transplantation.

Experimental transplantation in rodents has been used to understand much of what we know regarding SSC homing. For example, signaling through the CXCR4 expressed in SSCs is necessary for their homing to niches following transplantation and maintenance of the population in vivo during postnatal life (Yang et al., 2013; Kanatsu-Shinohara et al., 2012). CXCL12 secreted by Sertoli acts through CXCR4 on SSCs to regulate proliferation and inhibit RA-induced differentiation (Yang et al., 2013). Also, SSCs express $\alpha 6$ - and $\beta 1$ -integrin (Shinohara et al., 2000), a complex that forms the laminin receptor, and laminin is the primary component of the seminiferous basement membrane. Transplantation studies have shown that $\beta 1$ -integrin expressed by SSCs and Sertoli cells is necessary for retention of SSCs to their cognate niches (Kanatsu-Shinohara et al., 2008). Furthermore, $\beta 1$ -integrin is necessary for attachment of cultured spermatogonia to laminin-coated plates in vitro (Kanatsu-Shinohara et al., 2008). E-Cadherin (also known as Cadherin 1 or Cdh1) is also preferentially expressed by undifferentiated

Fig. 2 Model of the seminiferous tubule and SSC niche composition. SSCs nestled along the seminiferous membrane and below the blood-testis-barrier (BTB) are exposed to glial cell-derived neurotrophic factor (GDNF), fibroblast growth factor 2 (FGF2), C-X-C motif chemokine ligand 12 (CXCL12), and neuregulin 1 (NRG1) produced by the adjacent Sertoli cells. Peritubular myoid cells also produce GDNF. Leydig cells contribute colony stimulating factor 1 (CSF1) and insulin-like growth factor 1 (IGF1). Together, these factors as well as others yet to be identified regulate SSC survival, proliferation, self-renewal, and progenitor formation.

A_s , A_{pr} , and A_{al} spermatogonia and is likely a component of the SSC niche (Tokuda et al., 2007). However, $\alpha 6/\beta 1$ -integrin and E-cadherin are not solely expressed by SSCs. Therefore, further studies are necessary to identify niche-specific adhesion molecules that participate in SSC homing (Fig. 2).

Sertoli Cell Contributions to the SSC Niche

Sertoli cells are generally considered key contributors to the SSC niche. For example, experimentally increasing the number of Sertoli cells by approximately 50% in mice leads to a greater than threefold increase in the number of niches occupied by SSCs (Oatley et al., 2011). Sertoli cells are closely associated with spermatogonia. This association is first established with the formation of seminiferous cords during development and remains in mature seminiferous tubules into adulthood. Because SSCs reside in the basal compartment of the seminiferous epithelium, they are exposed to factors secreted by the interstitial cells and derived from the systemic circulation. Thus, the anatomical location of SSCs along the basement membrane and beneath the BTB is a defining characteristic of the mature SSC niche. Sertoli cells are also capable of acting as intermediates relaying systemic signals to the SSC niche. For example, the pituitary-derived gonadotropin follicle-stimulating hormone (FSH) acts on Sertoli cells leading to the secretion of growth factors that support the SSC niche.

FSH stimulates Sertoli cell production of one of the most well-known regulators of SSC function, glial cell line-derived neurotrophic factor (GDNF) (Tadokoro et al., 2002; Ding et al., 2011). Progressive exhaustion of spermatogenesis occurs in mouse models with a *Gdnf* null allele in a dosage-dependent manner, indicating that GDNF is necessary for SSC self-renewal and maintenance in vivo (Meng et al., 2000). Conversely, overexpression of *Gdnf* leads to the accumulation of undifferentiated spermatogonia (Meng et al., 2000). In primary cultures of mouse spermatogonia, GDNF is necessary for long-term survival as well as maintenance of regenerative capacity as measured via transplantation (Nagano et al., 2003; Kubota et al., 2004). GDNF is also necessary for the proliferation and survival of cultured spermatogonia from rats (Ryu et al., 2005), rabbits (Kubota et al., 2011), cattle (Oatley et al., 2016), and humans (Sadri-Ardekani et al., 2009; He et al., 2010), suggesting that GDNF is likely a conserved factor necessary for the maintenance and function of SSCs across most mammalian species. However, further transplantation studies are necessary to truly assess the requirement of GDNF in the maintenance of stem cell capacity in many of these species. GDNF signals through a complex of the RET receptor and GDNF family receptor $\alpha 1$ (GFR $\alpha 1$) present on SSCs as well as other A_s , A_{pr} , and A_{al} spermatogonia. Therefore, while GDNF is unequivocally necessary for survival and proliferation of SSCs and other undifferentiated spermatogonia, growth factors that specifically direct self-renewal or differentiation decisions by SSCs alone have yet to be determined.

Fibroblast growth factor 2 (FGF2) is another Sertoli-cell derived growth factor that is necessary for SSC maintenance. Co-supplementation of mouse primary spermatogonia cultures with FGF2 and GDNF leads to the long-term expansion of SSCs in vitro (Kubota et al., 2004; Kanatsu-Shinohara et al., 2005). Likewise, epidermal growth factor (EGF) has been shown to augment the actions of GDNF-induced proliferation and survival in cultures of spermatogonia (Kanatsu-Shinohara et al., 2005). However, neither FGF2 nor EGF can support SSCs alone; co-supplementation with GDNF is still necessary to maintain spermatogonial cultures (Kubota et al., 2004).

Interestingly, Sertoli cells also express factors that promote the formation of progenitors from SSCs. Neuregulin 1 (NRG1) is expressed by Sertoli cells in mice (Zhang et al., 2011) and peritubular myoid cells in rats (Zhang et al., 2011), and conditional inactivation of NRG1 in mice leads to the accumulation of undifferentiated spermatogonia, indicating a block in formation of differentiating spermatogonia (Zhang et al., 2011). Furthermore, rat germ cells express the NRG1 receptor ERBB3 and supplementation of culture media with NRG1 leads to the formation of spermatogonial chains, thus indicating progenitor formation (Hamra et al., 2007).

Interstitial Cells and Circulatory Contributions to the SSC Niche

The interstitial spaces of the testis are predominantly populated with Leydig cells, peritubular myoid cells, macrophages, and a network of blood vessels, all of which provide vital contributions to the SSC niche. Leydig cells are the predominant source of testosterone in the testis and do so in response to the pituitary-derived luteinizing hormone. Peritubular myoid cells line the seminiferous tubule as a smooth muscle-like layer to provide peristaltic action and structural support. Macrophages are the immune cells of the testis, separated from the advanced germ cells by the BTB. In addition to these primary functions, research suggests that testicular interstitial cells and the vasculature may play important roles in SSC function.

Leydig and some peritubular myoid cells—but not Sertoli cells—produce the SSC regulator colony stimulating hormone 1 (CSF1) (Oatley et al., 2009). Addition of CSF1 to cultures of spermatogonia also treated with GDNF and FGF2 leads to increased SSC concentration as measured by transplantation without altering spermatogonial proliferation, overall suggesting that CSF1 regulates SSC self-renewal activity specifically (Oatley et al., 2009). Also, *Csf1r* expression is enriched in SSCs (Helsel et al., 2017b), supporting the conclusion that CSF1 promotes SSC self-renewal.

Insulin-like growth factor 1 (IGF1) is another Leydig cell-derived factor that regulates the proliferation of numerous testicular cells, including SSCs. Also, the testicular vasculature is likely another source of IGF1. Addition of IGF1 to cultures of spermatogonia sustained with GDNF leads to the expansion of SSCs via proliferation (Kubota et al., 2004). The IGF1 receptor (IGF1R) is expressed by spermatogonia including SSCs and promotes DNA synthesis and proliferation through the G₂/M checkpoint (Potter and DeFalco, 2017).

In addition to Sertoli cells, peritubular myoid cells also produce GDNF (Chen et al., 2016). The mouse seminiferous epithelium can be roughly categorized into 12 sequential stages of germ cell development. Sertoli cells produce GDNF during stages IX through I, and peritubular myoid cells produce GDNF during stages II through IV (Potter and DeFalco, 2017).

Other Factors That Promote Progenitor Formation

Numerous studies agree that RA is the principal trigger for terminal differentiation of spermatogonia in the postnatal/adult testis. However, recent studies indicate that RA acts only on undifferentiated, nonstem cell spermatogonia, and the niche protects SSCs from local RA exposure (Lord et al., 2017). Thus, what factors promote asymmetrical or symmetrical formation of progenitors by SSCs? Studies utilizing primary cultures of murine undifferentiated spermatogonia have begun to answer this question. First, supplementation of spermatogonia cultures with either BMP4 or Activin A decreases SSC number and promotes the differentiation of spermatogonia (Pellegrini et al., 2003). Additionally, (as discussed above) NRG1 produced by the feeder cells in spermatogonial cultures leads to the formation of chains indicative of progenitor formation. Further studies are necessary to understand the SSC-specific responses to BMP4, Activin A, and NRG1 that promote progenitor formation while preventing exhaustion of the SSC pool.

Based on the aforementioned studies with cultured spermatogonia, progenitor formation is likely regulated through (1) temporal secretion of pro-differentiation factors by somatic or other germ cells, (2) the dynamic response to factors regulated intrinsically by SSCs, or (3) a combination of both. Recent studies have shed light on complexity of this regulation. Wingless-type MMTV integration site (WNT) signaling promotes the proliferation of progenitor spermatogonia in culture (Yeh et al., 2011) and WNTs are expressed in a stage-specific manner by Sertoli and interstitial cells that coincides with progenitor formation (Tokue et al., 2017). Interestingly, the WNT inhibitor SHISA6 has confers resistance to WNT signaling by a subset of spermatogonia believed to constitute SSCs (Tokue et al., 2017). Thus, the temporal regulation of pro-progenitor factors in combination with intrinsic control of SSCs to these responses, likely underscores the fate of some spermatogonia to form progenitors. Whether additional pro-progenitor or pro-self-renewal factors participate in this combinatorial regulation has yet to be determined.

Summary and Conclusions

As research continues to elucidate the composition of the SSC niche, our knowledge regarding the function and behavior of SSCs continues to broaden. This knowledge will continue to identify underlying causes of male infertility and generate new means of rectifying such ailments. Future studies focused on changes in the concentration of niche factors will illuminate the chemical, environmental, genetic, and physical factors that impact male fertility. For example, mice and humans normally begin to experience reproductive senescence and declining fertility with advanced age. Previous studies in mice found that serial transplantation at 3 month intervals maintained spermatogenesis in young recipients, suggesting that SSC self-renewal persists beyond the lifespan of mice and that niche breakdown likely contributes to the decline in spermatogenesis with age (Ryu et al., 2006). Thus, premature niche breakdown could underlie the clinical presentation of infertility among many men. Also, changes in niche factor concentration could help combat the detrimental side effects chemotherapeutics in men. For example, GDNF expression is elevated in Sertoli cells following busulfan treatment of mice (Ryu et al., 2006; Zohni et al., 2012). Therefore, additional growth factor supplementation could protect SSCs from depletion with cancer treatment.

Even with advances in our understanding of the SSC niche, our knowledge is still rudimentary, as evidenced by the fact that self-renewal of spermatogonial cultures can only be sustained for approximately 6 months (Helsel et al., 2017a). Therefore, current studies are actively searching for factors that sustain spermatogonia from several species with the hope of stably expanding an SSC pool for research and/or clinical application with techniques such as transplantation. In addition to pro-proliferative and pro-survival factors necessary for all undifferentiated spermatogonia like GDNF, FGF2, EGF, and IGF1, there are likely other SSC-specific growth-supporting factors yet to be identified. Likewise, the search continues for SSC-specific factors that regulate self-renewal and/or progenitor formation as well as the continued in vivo studies of previously identified factors such as CXCL12, CSF1, NRG1, BMP4, and Activin A.

With the great breadth of knowledge that has been gleaned from studies of the last few decades, several unanswered questions remain, so our understanding of SSC niche composition and SSC function will continue to evolve into the future.

Spermatogenic Cell Syncytium

Introduction

Connections of male germ cells by intercellular processes were described already in the 19th century by von La Valette-St. George (1865), Sertoli (1878), and von Ebner (1888). Transmission electron microscopy and live-cell imaging studies have provided a detailed description of intercellular bridge (ICB) assembly, changes in its structure in different phases of spermatogenesis and evidence for intercellular movement of molecules, granules, vesicles, and organelles via ICBs (Burgos and Fawcett, 1955; Fawcett et al., 1959; Dym and Fawcett, 1971; Huckins, 1978a; Weber and Russell, 1987; Ventelä et al., 2003). The bridge channel, that connects the syncytial cells, is no open space but it is filled by microtubules, endoplasmic reticulum, filaments, ribosomes, mitochondria, vesicles, and granules (Dym and Fawcett, 1971; Weber and Russell, 1987; Ventelä et al., 2003; Clermont and Rambourg, 1978). Their presence in the ICB channel suggests that cellular material is actively being transported between the interconnected cells.

The cells that are connected by ICBs are called a syncytium. Male germ cells enter and complete spermatogenesis in syncytia (Fig. 1). Cell fate decisions within the syncytium are shared and the whole clone either proceeds according to the strict spermatogenic program or undergoes apoptosis (Huckins, 1978b). Cytoplasmic contiguity, that the ICBs enable, is considered a prerequisite for synchronous spermatogenic progress of the clone. Compared to gap junctions, that connect cells in numerous tissues, ICBs (0.5–3 µm) are huge openings in the cell membrane that provide the basic framework to establish and maintain cytoplasmic homogeneity within the syncytium (Weber and Russell, 1987).

The current understanding is that ICB formation is a distinctive form of cytokinesis (Greenbaum et al., 2011). Cytokinesis can be divided into three phases: selection of the site for cell division, cleavage furrow ingression and formation of a contractile ring, and abscission of the midbody (Greenbaum et al., 2011; Fededa and Gerlich, 2012). From a germ cell point of view, the last step is the most interesting one. While midbodies and ICBs are involved in every cell division, in somatic cells they are short-lived, whereas in germ cells ICBs are stabilized, which is a prerequisite for syncytial development, spermatogenesis, and male fertility. Development of a syncytium has been conserved in the male germ-line for over a billion years, from invertebrates to humans (Burgos and Fawcett, 1955; Rasmussen, 1973). While lack of spermatogenic syncytia results in meiotic failure and infertility, mutations in cytokinetic proteins can cause formation of multinucleated germ cells that are able to develop to postmeiotic phase emphasizing the importance of intercellular connection for spermatogenesis (Holstein and Eckmann, 1986; Carmena et al., 1998; Brill et al., 2000; Greenbaum et al., 2006).

Due to their wide diameter, ICBs, at least on theoretical level, enable exchange and equal distribution of cytoplasmic components and organelles or their structural components, granules, and vesicles (cytomixis). In nondividing germ cells the nuclear envelope prohibits intracolon exchange of nuclear material via ICBs. In prometaphase to late telophase, when the nuclear membrane is lacking or is just being reassembled, a specific structure called bridge-partitioning complex preserves genomic integrity and transiently closes ICBs to avoid the drift of chromatin to neighboring cells (Miething, 2003).

Many hypotheses have been proposed as to address the function and significance of germ cell intercellular bridges (reviewed by Guo and Zheng, 2004). According to the “cytoplasm sharing” hypothesis passage of cytoplasmic constituents via ICBs ensures synchronous spermatogenesis within the syncytium. Another hypothesis suggests that intercellular traffic via ICBs is needed to even out stochastic and gene content-derived (after meiotic segregation) differences in the transcriptome and permit genotypically haploid cells to function in a phenotypically diploid manner (Braun et al., 1989). Two examples will clarify the point: (1) some genes that are essential for postmeiotic spermatogenesis are located in the sex chromosomes. Haploid spermatids possess just one sex chromosome (say X), which makes them dependent on sharing of gene products derived from the other sex chromosome (Y); (2) Not all alleles are good and sharing of the gene products encoded by normal alleles might help to shelter from the undesired effects. According to the “critical coordination” hypothesis rapid ICB-mediated signal transfer is needed at critical steps (such as A₁ transition, discussed below) during spermatogenesis to coordinate the process. “Gamete equivalence” hypothesis emphasizes the need to create gametes that are uniform in structure and morphology (similar acrosomes, for instance Ventelä et al., 2003) as gamete heterogeneity associates with fertility problems. Equivalence and high overall sperm quality would result from cytoplasm sharing and elimination of heterogeneity that the ICBs allow for. Finally, LeGrand sees ICBs as a means for the germ cells to monitor the internal state of their sister cells for emergence of self-promoting genes, and, if needed, induce apoptosis of the whole cyst (LeGrand, 2001).

All these hypotheses provide a plausible explanation for the existence of ICBs in the germ-line but it deserves to be mentioned that ICBs only provide wide channels and do very little per se to contribute to the outcomes discussed above. For cytomixis to occur, the interconnected cells need to build the cytoskeletal infrastructure and molecular motors to make the cargo moving. To ensure even but not random distribution of cytoplasmic constituents the task needs to be assigned to specialized macromolecules, such as the chromatoid body, that are active at the ICB interface (Ventelä et al., 2003).

This article provides a concise review of our current knowledge about the formation male germ cell syncytium and its significance for spermatogenesis. It will focus mainly on mouse, rat and *Drosophila* where the most study has been completed.

Fig. 1 Spermatogenesis and formation of spermatogenic cell syncytium in the mouse. The only postnatal germ cell type lacking a cytoplasmic connection is the A-single (A_s) spermatogonium. Division of A_s produces A-paired (A_{pr}), a cyst of two cells. Cytokinesis in the male germ-line is incomplete and each cell division therefore doubles the syncytial length. Accordingly, mitosis of A_{pr} gives rise to A-aligned4 (A_{al4}), a 4-cell cyst, then A_{al8} and A_{al16}. These cells are called undifferentiated spermatogonia (gray cells), the stem and progenitor cells of the adult mouse testis. They transit into A₁, the first subpopulation of differentiating spermatogonia (blue cells) and enter spermatogenesis as a cyst of 16 cells (shown) or as A_s or shorter cysts. A₁ spermatogonia undergo six mitotic divisions before the onset of meiosis as primary spermatocytes (khaki cells). Each division doubles the cyst length (column on the left). Meiotic divisions quadruple the syncytial length, give rise to spermatids (purple cells) and bring the theoretical maximum size for a spermatogenic cyst to 4096 cells. In practice, such lengths are not achieved and the cyst occasionally splits. This color key is maintained throughout this article. Inset shows whole-mount staining of adult mouse seminiferous tubule at stages II–VI of the seminiferous epithelial cycle. PLZF (promyelocytic leukemia zinc finger, green) is expressed in A_{pr} and A_{al4-16} undifferentiated spermatogonia, whereas LIN28a (red) stains strongly only A_{al8-16}. Low expression of both is seen in intermediate/type B spermatogonia on the background.

Ring Canals in *Drosophila*

Germ cell division in the *Drosophila* germ-line is incomplete and results in the formation of a 16-cell cyst in which the diploid germ cells are interconnected by stable cytoplasmic bridges called ring canals (RC). Formation of RCs results from cessation of contractile ring constriction and consequent cleavage furrow arrest (Hime et al., 1996; Robinson and Cooley, 1996; Huynh and St Johnston, 2004). Further development of the germ cell syncytium is sex-dependent, and in the female, one of the syncytial cells is selected as the oocyte and the rest (15 cells) will become nurse cells that eventually transfer most of their cytoplasmic material to the oocyte (Huynh and St Johnston, 2004). In the male, the cyst undergoes meiotic divisions to give rise to a syncytium of 64 haploid germ cells (Fig. 2) (Huynh and St Johnston, 2004). A characteristic feature of the *Drosophila* germ-line is the fusome, a specialized and highly vesiculated cytoplasmic structure that connects the cells in the germ cell cyst via RCs. The fusome originates from a spectro-some, which is a spherical structure present in germ-line stem cells (Lin et al., 1994). The function of the fusome is not well understood but it may have a role in coordination of cell division during *Drosophila* gametogenesis (Lin et al., 1994). Interestingly, in the female germ-line the fusome is disintegrated upon oocyte specification but in the male it persists until late spermiogenesis and might serve to align spermatid flagella within a cyst (Hime et al., 1996; Lin et al., 1994). To our knowledge, an equivalent structure does not exist in mammals.

Despite the nomenclature, RCs of the two sexes are structurally different and mature male and female RCs share only a few structural components, including MKLP1 (mitotic kinesin-like protein 1; named Pavarotti in *Drosophila*), a key component in mammalian midbodies and ICBs, too (Eikenes et al., 2013). Besides the germ-line, RCs also connect some populations of somatic cells in

Fig. 2 Spermatogenesis and formation of the spermatogenic cyst and the fusome in *Drosophila*. The gonialblast (on the left) divides four times to produce a 16-cell spermatogonial cyst that enters meiosis. The meiotic divisions give rise to a cyst consisting of 64 spermatids. Ring canals (RCs, green) are formed as a result of cleavage furrow arrest and consequential incomplete cytokinesis. Fusome (orange) connects all the cells in a cyst via RCs. It is a derivative of the spectrosome, a spherical structure located in the cytosol of germ-line stem cells (predecessors of gonialblasts). RC composition is temporally regulated and while many proteins are ubiquitously present in RCs (pTyr, MKLP1, Myosin II, Anillin, Sep1, Sep2, Mucin-D), some are lost (F-actin and Cindr) and others are introduced (Pnut) during spermatogenesis.

Drosophila. Somatic RCs between ovarian follicle cells and more restrictedly in larval wing imaginal discs allow intercellular diffusion of cytoplasmic proteins (McLean and Cooley, 2013).

RCs in *Drosophila* are tyrosine phosphorylated, and emergence of phosphotyrosine (pTyr) epitopes in the late telophase is considered the first step in the RC assembly (Robinson and Cooley, 1996). Proteins containing pTyr accumulate in the ring canal that already contains contractile ring F-actin and myosin II, scaffold protein Anillin and septins (Sep1, Sep2), that can self-assemble into rings (Robinson and Cooley, 1996; Kinoshita et al., 2002). Src64 kinase has been proposed to play a key role in controlling tyrosine phosphorylation at the site of RC formation and in definition of RC diameter (Eikenes et al., 2015). However, Src64 deficient male flies are fertile, which implies that other proteins might compensate for loss of Src64 (Dodson et al., 1998). Upon maturation F-actin and scaffold protein Cindr are removed from the RC, and the contractile ring is consequently disassembled. This is probably a key step in incomplete cytokinesis and stabilization of RCs, and it coincides with the mitosis to meiosis shift in both sexes (Eikenes et al., 2013). Both Cindr and F-actin are translocated to the fusome and they are vitally important proteins for its expansion (Eikenes et al., 2013). The mature postmitotic RC of *Drosophila* male germ-line consists of pTyr-containing proteins, Anillin, septins (Sep1, Sep2, Pnut), MKLP1, Zipper (nonmuscle myosin II heavy chain), and glycoprotein Mucin-D (Fig. 2) (Carmenta et al., 1998; Hime et al., 1996; Eikenes et al., 2013; Cooley, 1998; Kramerova and Kramerov, 1999). Interestingly, RCs of the *Drosophila* male germ-line are structurally similar to somatic RCs. Despite their relatively small diameter—when compared to oogenesis-associated RCs (up to 10 μm)—they permit intercellular movement of cytoplasmic particles to equilibrate protein content among transcriptionally mosaic cells, and are essential for fertility (Cooley, 1998; McLean and Cooley, 2014). Fragmentation of spermatogonial cysts via abscission of intercellular connections result in dedifferentiation of differentiation-committed germ cells—a mechanism reminiscent of replenishment of mammalian testis stem cell niche, as discussed below (Brawley and Matunis, 2004).

Intercellular Bridges in Mammals

Spermatogenic Cell Expansion and Stabilization of the Intercellular Bridge

Complete cytokinesis is an exception in the mammalian male germ-line under steady state conditions. The only germ cell type in the adult testis that is not connected to another cell by a cytoplasmic connection is the A-single (A_s) spermatogonium (Fig. 1). According to the A_s theory from 1971 by Huckins and Oakberg, the A_s spermatogonia function as spermatogonial stem cells during steady state spermatogenesis (Huckins, 1971; Oakberg, 1971; de Rooij and Russell, 2000). More recent research has complicated the situation a bit and among other things it has shown that (1) considerations about whether A_s divisions are symmetrical (dividing into similar cells) or asymmetrical (dividing into dissimilar cells) are obsolete as division of A_s is in ~95% of the cases incomplete and the daughter cells are connected by a cytoplasmic bridge (A-paired, A_{pr}), that (2) A_s can commit to differentiate without preamplification, and that (3) undifferentiated type A (A_{undiff} , A_s and cysts of up to 16 cells, Fig. 1) spermatogonia retain the ability to function as stem cells after fragmentation of the cysts under steady state spermatogenesis and especially during repopulation of the seminiferous epithelium after cytotoxic stress or transplantation (Nakagawa et al., 2007, 2010; Hara et al., 2014). Formation of an ICB between the progeny of an A_s division (A_{pr}) would lead to exhaustion of the A_s population were it not replenished from alternative sources. Indeed, fragmentation of A_{pr} and A_{al4} (a cyst of four cells) is relatively common and gives rise to new A_s spermatogonia, whereas their division is always incomplete and doubles the syncytial length (Fig. 3) (Hara et al., 2014). The mechanisms that control stability and breakdown of ICBs and consequential fragmentation of A_{undiff} syncytia have not been well characterized.

Fig. 3 Dynamics of the stem and progenitor spermatogonia during mouse spermatogenesis. GFRa1-positive (GDNF family receptor alpha 1) stem cells (blue plane) actively interconvert between short syncytial and single cell states through incomplete cytokinesis and cyst fragmentation (*) and maintain the self-renewing spermatogonial population, or are primed to differentiate and enter the transit-amplifying progenitor state (green plane). Under steady state spermatogenesis, the progenitor cells are bound to enter spermatogenesis but they retain the capacity for self-renewal via fragmentation in case of a need to repopulate the seminiferous epithelium. Once entered spermatogenic process as A₁ spermatogonia (orange plane), germ cells are committed to differentiate according to a rigid time-scaled program.

Differentiation propensity within the A_{undiff} population is associated with chain length. Increased A_{undiff} cyst length is typically connected with a higher likelihood to differentiate with a concomitant upregulation of a group of markers (such as Ngn3 [neurogenin 3], Sox3 [Sry-box 3], and RARγ [retinoic acid receptor gamma], and downregulation of others (most notably glial cell-line derived neurotrophic factor [GDNF] receptor GFRa1 [GDNF family receptor alpha 1]) (Nakagawa et al., 2010; Raverot et al., 2005; Ikami et al., 2015). As described above, GFRa1-expressing A_s, A_{pr}, and A_{al} spermatogonia comprise a single stem cell pool, in which cells continually and reversibly interconvert between singly isolated and short syncytial states through incomplete cell division and fragmentation of syncytia. Ngn3 positive cells are recruited from this pool by differentiation-priming activity of the Wnt/beta-catenin pathway (Fig. 3) (Nakagawa et al., 2010; Hara et al., 2014; Takase and Nusse, 2016; Tokue et al., 2017). While these Ngn3-positive progenitor spermatogonia retain ability for self-renewal, they are destined to differentiate under steady state conditions (Nakagawa et al., 2007, 2010). Therefore, similar to *Drosophila*, stabilization of the ICB can be regarded as a prerequisite for differentiation commitment in the mammalian male germ-line (Brawley and Matunis, 2004). Acquisition of RARγ expression equips the Ngn3-positive progenitor spermatogonia with a competence to respond to differentiation-inducing stimuli, most notably retinoic acid (RA) (Ikami et al., 2015). RA-induced transition of A_{undiff} spermatogonia into type A₁ differentiating spermatogonia is considered the onset of spermatogenesis due to its irreversible nature (Fig. 3). A_{undiff} to A₁ transition is characterized by notable changes in spermatogonial transcriptome and induction of Kit and DNA methyltransferases that act on the committing cell epigenome (Schrans-Stassen et al., 1999; Shirakawa et al., 2013). It is not known whether architecture of the ICB changes as a result of spermatogonial differentiation commitment but stabilization of its structure might contribute to inability of differentiating spermatogonia to revert to the naïve state.

Having transitioned into a type A₁ spermatogonium, the destiny of a male germ cell is fixed and it undergoes spermatogenic differentiation according to a rigid time-scaled program, or perishes by apoptosis (Fig. 1). In the mouse, A₁ spermatogonia first divide six times mitotically (A₁ → A₂ → A₃ → A₄ → intermediate → B → spermatocyte) before entering meiosis as preleptotene spermatocytes. Meiotic divisions quadruple the number of germ cells resulting in a theoretical 4096-fold amplification in cell number during the course of spermatogenesis (Fig. 1). The progeny of spermatogenic cell mitotic and meiotic divisions are connected by ICBs. However, syncytia of these cells occasionally split and the maximal observed size for a spermatogenic cell syncytium (spermatids in this case) is 650 cells (Ren and Russell, 1991). Cell fate decisions within a syncytium are shared and all the cells in the cyst coordinately progress on the spermatogenic pathway.

Germ cells are fully dependent on somatic Sertoli cells for survival, maintenance and differentiation (Franca et al., 2016). As spermatogenesis progresses the germ cells translocate from the basal lamina of the seminiferous epithelium, between the Sertoli

cells to the lumen of the seminiferous tubule. Having detached from the basal lamina as leptotene primary spermatocytes, the germ cells are engulfed by Sertoli cells and they need to traverse the Sertoli cell barrier (SCB, also known as the blood–testis barrier, BTB) to the immune-privileged adluminal side of the seminiferous epithelium in order to continue maturation. The translocation through the Sertoli cell cytoplasm and SCB is a remarkable effort when keeping in mind that the germ cells do not traverse SCB as solitary cells but as a sieve-like syncytium that can consist of at least some tens and maybe hundreds of cells (theoretically 1024 cells), and the clone spans a number of Sertoli cells. The junctions that form the SCB remain functional during the spermatocyte translocation and maintain the integrity of the SCB. This requires the formation of a transient intermediate compartment where the leptotene spermatocytes are bound by basal and apical tight junctions (Smith and Braun, 2012). The cytoplasmic connection between maturing germ cells provided by the ICB is maintained until the end of spermatogenesis and mature elongated spermatozoa are disengaged from the seminiferous epithelium as single cells (spermiation). ICBs are lost upon spermiation and they are not observed to connect the residual bodies, the excess cytoplasm of spermatozoa, that are phagocytosed by the Sertoli cells (Weber and Russell, 1987).

ICBs are dynamic and there are rearrangements in their structure at various steps during spermatogenesis, especially in spermiogenesis (Weber and Russell, 1987). This reflects to ICB dimensions that vary considerably in different phases of spermatogenesis. While ICB length generally fluctuates between 0.5 and 1 μm during the course of rat spermatogenesis, the ICB diameter undergoes spermatogenic cell type dependent changes. In differentiating type A spermatogonia the ICB diameter ranges from 0.5 to 1 μm ; in intermediate and type B it is about 1.3 μm . The ICBs that connect spermatocytes are slightly wider. At the onset of spermiogenesis, ICBs of step 1 spermatids are approximately 1.8 μm in diameter. There is a gradual increase in diameter of spermiogenic cell ICBs and by step 18 they reach width of 3.0 μm . At the last step of spermiogenesis (step 19) ICBs constrict to about 2.0 μm in diameter (Weber and Russell, 1987).

ICBs are not characteristic only to postnatal germ cells but they also exist in embryonic germ cells. Upon arrival to the bipotential gonad on embryonic day 10.5 (E10.5) most of the primordial germ cells (PGCs) exist as single cells and only 2% are found in groups of more than two cells (Pepling and Spradling, 1998). In the following days they proliferate actively to form cysts and enter mitotic quiescence at around E14.5 (McLaren, 1984; Tam and Snow, 1981). These cells, called gonocytes, are connected by ICBs but these bridges are weak and the gonocyte cysts partially fragment by birth (Greenbaum et al., 2009; Lei and Spradling, 2013). Partial fragmentation leads to appearance of single cells and short cysts (Lei and Spradling, 2013). Independent of the germ cell identity (embryonic, stem/progenitor, mitotic, meiotic or postmeiotic) formation of ICBs depends on one protein preferentially expressed in germ cells: TEX14 (testis-expressed gene 14) (Greenbaum et al., 2006, 2007, 2009; Iwamori et al., 2012).

Mechanism of Germ Cell ICB Formation

Formation of an intercellular bridge is an elemental part of every cell division event. However, in somatic cells, ICB is rapidly cleared at the end of cytokinesis and cytoplasmic contiguity between the nascent daughter cells is lost. Formation of a stable ICB as seen in germ cells can be regarded as a modification of normal cell division that involves stabilization of the midbody, a bulge that lies in the middle of ICB. The midbody matrix consists of numerous protein complexes, including the centralspindlin complex (Fededa and Gerlich, 2012). Centralspindlin is a heterotetramer of MLKP1 and RacGAP1 (Rac GTPase-activating protein 1, also known as MgcRacGAP or CYK-4) and it interacts with the cytoskeleton and is involved in recruitment of the midbody abscission machinery as discussed below (White and Glotzer, 2012). Binding of centralspindlin to CEP55 (centrosomal protein 55), a dimeric coiled-coil protein, is considered the first step toward midbody abscission (Zhao et al., 2006). CEP55 is a protein scaffold that brings centralspindlin in contact with ESCRT-I (endosomal sorting complexes required for transport) complex via interaction with ALIX (ALG-2 interacting protein X) and TSG101 (tumor susceptibility gene 101) subunit (Morita et al., 2007; Carlton and Martin-Serrano, 2007). This, in turn, results in recruitment of the abscission machinery in the form of ESCRT-III complex (Fig. 4A) (White and Glotzer, 2012). MLKP1 and RacGAP1 colocalize with TEX14 in the germ cell ICB in mouse and man (Greenbaum et al., 2007; Naud et al., 2003). The mechanism of TEX14 action to block midbody abscission and stabilize the ICB is to prevent recruitment of ESCRT-I. This is achieved by physical inhibition of CEP55 interaction with ALIX and TSG101 (Fig. 4B) (Kim et al., 2015). TEX14 is indispensable for germ cell ICB formation (Greenbaum et al., 2006).

TEX14, ALIX, and TSG101 all carry an AxGPPx3YxPP (Ala793, Gly795, Pro796, Pro803, and Pro804) motif that binds to EABR (ESCRT and ALIX-binding region) sequence of CEP55 (Kim et al., 2015). The affinity of CEP55-EABR for the TEX14 AxGPPx3YxPP motif is 3–10 times higher than toward the same motif in ALIX or TSG101. In addition, interaction of TEX14 with CEP55-EABR is more stable than that of ALIX. To further promote TEX14-CEP55 interaction, TEX14 is recruited to the midbody before CEP55, whereas ALIX and TSG101 enter midbody later than CEP55 during somatic cell cytokinesis. On top of higher affinity and more stable interaction, this mechanism gives TEX14 a competitive advantage for CEP55-EABR interaction over ALIX and TSG101 (Kim et al., 2015; Iwamori et al., 2010). As a result ALIX1 is displaced from the midbody, ESCRT-I and ESCRT-III will not get recruited and TEX14-CEP55 interaction stabilizes the cytoplasmic connection, and tethers the daughter cells. New proteins are then recruited to the nascent stable ICB (Fig. 4B).

In spermatogonial and spermatocyte early bridges TEX14 forms an inner ring in the midbody matrix and is surrounded by an outer ring of centralspindlin and septins 2, 7, and 9 (putative orthologs of *Drosophila* Sep1, Pnut and Sep2, respectively) (Greenbaum et al., 2007; Pan et al., 2007). TEX14 is able to interact with itself—a characteristic, which probably facilitates the formation of a ring-like structure (Iwamori et al., 2010, 2011). As the ICB matures, the TEX14 ring starts to expand and it eventually merges with the outer ring (Greenbaum et al., 2007). There is a concomitant increase in ICB diameter, and removal of septins leaves

Fig. 4 Midbody abscission vs. stabilization of the intercellular bridge. (A) In somatic cells (or TEX14 deficient germ cells) ESCRT-III is recruited into the midbody via centralspindlin-CEP55-ALIX-TSG101 interaction, and the midbody is abscised resulting in complete cytokinesis and separation of the two daughter cells. (B) In germ cells, TEX14 interacts with the CEP55 EABR sequence, that is needed for ALIX/TSG101 dependent ESCRT-III recruitment. As a result ALIX/TSG101 and ESCRT-III subunits never enter the midbody, the abscission is blocked, and new proteins (*star* and *diamond*) required for ICB stabilization and maturation are recruited. The mitotic spindle (blue lines) is disassembled later on.

TEX14, CEP55, MKLP1, RacGAP1, pericentrin, delta-tubulin, and actin the role as the structural framework of mature ICBs (Greenbaum et al., 2006, 2007; Chang et al., 2010; Kato et al., 2004; Russell et al., 1987). Maturation of ICBs is associated with involvement of new proteins in spermatocytes and spermatids, such as keratin 5, HSF2 (heat shock factor 2), protocadherin-a3, and plectin (Fig. 5) (Tres et al., 1996; Alastalo et al., 1998; Johnson et al., 2004; Guttman et al., 1999). Unlike in *Drosophila*, Anillin never becomes a part of the stabilized ICB and it is removed from the midbody as TEX14 enters it (Greenbaum et al., 2007). RBM44, an RNA-binding protein with a hypothesized function in RNA transport between germ cells via ICBs, is transiently expressed in mature spermatocyte ICBs and colocalizes with TEX14 (Iwamori et al., 2011). RBM44 is lost from ICBs upon completion of meiosis and it is not needed for ICB formation; neither is its action essential for spermatogenesis. RBM44 deficient mice develop ICBs normally, they are fertile and, for an unknown reason, produce significantly higher number of sperm than wild-type control males (Iwamori et al., 2011). Gonocyte ICBs are typical early bridges with clear outer and inner rims of MKLP1 and TEX14, respectively (Greenbaum et al., 2009).

Fig. 5 Maturation of the intercellular bridges. As a result of ICB stabilization the mitotic spindle (dotted blue line) is disassembled. In early spermatogonial and spermatocyte ICBs there are two discernible rings: inner ring of TEX14 (red) and an outer centralspindlin ring (green, MKLP1 + RacGAP1). As these bridges mature, septins are lost and the inner ring expands and merges with the outer ring. In general, the ICB diameter grows as spermatogenesis proceeds and reaches a width of 3 μm in elongating spermatids. ICBs undergo constant reorganization in their structure and while some proteins are universally present in ICBs (TEX14, centralspindlin, CEP55, and actin) some are more specific: HSF2 and δ-tubulin localize only to late meiotic and postmeiotic ICBs, RBM44, and keratin 5 in mature spermatocyte ICBs, and protocadherin-a3 and plectin are exclusively present in late spermiogenic ICBs.

Germ cell cytokinesis is considered a deviation from normal (somatic) cytokinesis and, apart from the fate of the midbody, it is mechanistically highly if not completely similar to it. In TEX14 deficient mice midbody formation takes place normally in germ cells, which indicates that it is not a TEX14-dependent process (Greenbaum et al., 2007). The mechanism of its abscission in TEX14-deficient germ cells has not been characterized in detail but it is likely that, when TEX14 is not present, ESCRT III is recruited via an CEP55-ALIX-TSG101-dependent mechanism and cytokinesis is completed in a somatic cell manner (Fig. 4) (Greenbaum et al., 2007; Kim et al., 2015). While TEX14 is indispensable for ICB formation in mammalian germ cells, ectopic expression of TEX14 in somatic cells did not initially result in stabilization of ICBs (Greenbaum et al., 2007). However, overexpression of TEX14 leads to establishment of stable ICBs in somatic cells indicating that TEX14 is the only germ cell specific protein needed to block midbody abscission (Iwamori et al., 2010).

Intercellular Bridges and Fertility

There are two knock-out mouse models that illustrate the crucial connection between ICBs and fertility: TEX14 and germ cell specific RacGAP1 null mice both lack ICBs and fail to sire offspring (Greenbaum et al., 2006; Lores et al., 2014). In TEX14 null testes spermatogenesis proceeds to spermatocyte stage but germ cells fail to complete meiosis and no postmeiotic cells exist (Greenbaum et al., 2006). A closer look at the meiotic cells reveals that most early primary spermatocytes undergo apoptosis and very few pachytene spermatocytes are observed (Greenbaum et al., 2006). Interestingly, undifferentiated and differentiating spermatogonial populations look overtly normal regardless of loss of ICBs (Greenbaum et al., 2006). Accordingly, and due to relative enrichment of spermatogonia because of severe depletion of meiotic and postmeiotic cells, genes associated with undifferentiated spermatogonia (with the peculiar exception of GDNF target genes) and early differentiating germ cells markers are upregulated in TEX14 KO testes, whereas pan-germ cell marker Vasa is expressed at a lower level than in control testis (Iwamori et al., 2012). It is possible, however, that lack of ICBs in premeiotic germ cells interferes with a process that is needed to prepare the germ cells for meiosis, and therefore contributes to meiotic failure in TEX14 null testis and partially explains the TEX14 null phenotype.

Conversely, conditional RacGAP1 knock-out mice show impaired spermatogenesis and infertility. The phenotype is, however, more complex and the severity of spermatogenesis defect ranges from normal-looking tubule to Sertoli cell only phenotype probably due to incomplete Cre-mediated recombination (Lores et al., 2014). Interestingly, lack of RacGAP1 does not only lead into lack of ICBs but appearance of multinuclear germ cells suggesting that there is a problem in centralspindlin formation, and accordingly in cytoplasmic constriction (Lores et al., 2014). The reproductive phenotype therefore originates to a certain extent from inability of midbody establishment, not instability of the nascent ICB. Since most germ cells in the RacGAP1 null testis contain just one nucleus, it is likely that in most cases the cleavage furrow fully ingresses and the midbody is abscised. Variable penetrance of the used Cre promoter and inconsistent outcome of germ cell cytokinesis, however, make the results challenging to interpret. For these reasons, TEX14 null mice provide a better model to address the question about ICB significance for spermatogenesis and fertility. An important conclusion can still be drawn: establishment, maintenance, and stabilization of intercellular bridges are crucial for fertility.

Instability of ICBs and Maintenance of Spermatogonial Stem Cells

According to a model proposed by Shosei Yoshida and coworkers (discussed in detail above) the stem cell potential within the testis resides primarily in GFR α 1-positive single cells and short syncytia (stem), and latently in Ngn3-positive undifferentiated spermatogonia that preferably exist as longer syncytia (progenitor) (Fig. 3) (Nakagawa et al., 2007, 2010; Hara et al., 2014). The former population actively interconverts and exists as single cell or short syncytial states, whereas Ngn3-positive do not usually fragment, and under steady state conditions instable ICBs are therefore observed principally within the GFR α 1-positive A_{undiff} subset (Hara et al., 2014). From this point of view one might consider that loss of ICB formation ability (as observed in TEX14 null mice) would result in stem cell enrichment. Quite on the contrary, however, expression of GDNF-regulated genes is downregulated in TEX14 deficient testis. Despite these findings, there is not a stem cell maintenance defect in the TEX14 knock-out testis (Greenbaum et al., 2006). Interestingly, maintenance of TEX14 null SSPCs (spermatogonial stem and progenitor cells, the in vitro term for A_{undiff}) is compromised in vitro (Iwamori et al., 2012). This is probably due to a proliferation defect in these cells because their transcriptome is nearly identical to control SSPCs (Iwamori et al., 2012). Unfortunately, it is not known if TEX14 deficient SSPCs are transplantable and whether their capacity to home into the testis stem cell niche and form nascent colonies is normal. Despite poor proliferation in vitro, maintenance of spermatogonia at least up to 1 year of age in vivo suggests that TEX14 null A_{undiff} are able to self-renew for an extended period of time. ICBs also function as a cytoskeletal organizer and in TEX14 deficient SSPCs the architecture of the cytoskeleton has altered dramatically, which is bound to affect cell physiology (Iwamori et al., 2012).

While complete loss of ICBs is deleterious to fertility, increased instability of A_{undiff} syncytia, their consequent fragmentation and higher incidence of A_s spermatogonia is associated with improved life-time fertility, as observed in JMJD3 (Jumonji domain containing-3) deficient mice (Iwamori et al., 2013). JMJD3, a H3K27 (histone 3 lysine 27) demethylase, is an epigenetic modifier and it regulates stem cell fate and differentiation in a number of cell lineages (reviewed by Burchfield et al., 2015). JMJD3 is not needed for differentiation in the male germ-line, but it plays a role in the maintenance of ICBs and reduction of *Jmjd3* is considered to increase the number of spermatogonial stem cells via an unknown, allegedly TEX14-independent, mechanism (Iwamori et al., 2013). In cultured SSPCs, knock-down of *Jmjd3* leads to increased number of nascent colonies and alteration of colony morphology

from a grape-like to compact cluster-like appearance. The former finding can be explained by higher instability of ICBs or improved stemness of SSPCs (probably two sides of the same coin), but the latter one is intriguing because a similar morphological change is associated with SSPC reprogramming into a pluripotent state (Kanatsu-Shinohara et al., 2004). Enlarged testis size and prolonged fertility in JMJD3 deficient mice are likely secondary to enhanced self-renewal of A_{undiff} —an untested hypothesis supported by the in vitro findings, too. It can be concluded from the above studies, that formation of short-lived unstable syncytia and interconversion between single cell and short syncytial states is a dynamic feature of testis stem cell niche, and probably required for normal fertility.

Concluding Remarks

While CEP55-TEX14 interaction is indispensable for formation and maintenance of stable ICBs in mammals, the molecular mechanisms responsible for structural rearrangements in and around the nascent ICB are largely unknown. As discussed above, the dimensions and architecture of early intercellular bridges typical for gonocytes and spermatogonia differs remarkably from the mature ones that are seen in spermatids. What is more, spermiogenic ICBs are under constant process of remodeling but the identities of the proteins involved in these events are not known (Weber and Russell, 1987). Postformation functions of TEX14 are obscure but it has been speculated that it might work as a protein scaffold to recruit other bridge components (Greenbaum et al., 2006). Interestingly, despite obvious similarity between kinase-like domain of TEX14 and kinase domain of Src64, a kinase that is needed to induce RC formation in *Drosophila* (see above), the kinase activity of TEX14 is poor and TEX14-mediated phosphorylation of tyrosine or threonine residues therefore hardly plays a role in the ICB development (Greenbaum et al., 2006; Eikenes et al., 2015). Controlled instability of ICBs within the testis stem cell niche is probably required for maintenance of life-long male fertility—another hypothesized function assigned to germ cell ICBs. What are the factors that destabilize the A_{undiff} ICBs and how they mechanistically contribute to fragmentation of short GFRa1+ cysts await identification and clarification. Although germ cell ICBs have been studied for over 150 years, very little is known about their formation and function at the molecular level. There is a dire need for more research on these unique and fascinating intercellular connections.

The Seminiferous Epithelial Cycle and the Stages of the Seminiferous Epithelium

The development of male germ cells in the seminiferous epithelium can be divided into three phases: (1) mitotic phase, characterized by mitotic divisions of spermatogonia; (2) meiotic phase, including genetic recombination and two meiotic divisions that quadruple the cell number; and (3) spermiogenic phase, the complex differentiation cascade of postmeiotic haploid germ cells that eventually gives rise to mature spermata with an acrosome and a flagellum. The sequential progress of these phases is strictly regulated in time and space and spermatogenic cell differentiation through these phases is coordinately controlled within and between the germ cell syncytia present at a specific tubular area.

Histology of testicular tissue and seminiferous tubules may seem complex at first. Germ cells of varying morphology are situated inside the seminiferous tubule in a complex organization that does neither display any obvious hierarchy among the intermingled populations of germ cells nor a repetitive pattern of layering. However, the germ cells are organized in a strict order. Cross-sections of individual tubules within one histological specimen include areas that look similar and host the same populations of germ cells with a specific morphology. These recurring cellular associations, also known as the stages of the seminiferous epithelial cycle, are in constant progress as the germ cells are continually developing and their characteristics (cell shape, size, ploidy) change over time (Fig. 1). If the tissue were alive one could follow the gradual development of the cell associations and notice that after a specific interval the cross-section has reached the original appearance, and is said to have completed a cycle of the seminiferous epithelium (used interchangeably with “spermatogenic cycle,” “seminiferous cycle,” and “seminiferous epithelial cycle” in the literature) (Leblond and Clermont, 1952; Oakberg, 1956).

In rodents with a high number of premeiotic germ cell mitoses, the stages follow each other in a numerical order along the length of the seminiferous tubule, and form the spermatogenic wave, or the wave of the seminiferous epithelium. In human and primates, this kind of segmental arrangement of stages is not observed due to low amplification of differentiation-committed spermatogonial cells. This makes histological studies of human spermatogenesis considerably harder as a cross-section of the seminiferous tubule typically contains two to four stages, whereas in rodents it is uncommon to have more than one stage per cross-section (Amann, 2008). In most species, including man and mouse, the seminiferous cycle is subdivided into 12 stages (marked with Roman numerals I–XII) (Fig. 2) (Leblond and Clermont, 1952; Muciaccia et al., 2013). The stage classification is based primarily on gradual development of the acrosome in spermatids, the postmeiotic germ cells. In rodents, the segmental arrangement of the stages enables identification and isolation of stages based on their light absorption characteristics (Parvinen, 1982; Toppari and Parvinen, 1985; Kotaja et al., 2004).

It needs to be stated clearly that the morphological characteristics of the germ cells present at a given stage, or the number of stages are arbitrary and defined by morphology. The stages do neither have any biological relevance to the progression of the spermatogenic process per se, nor do they represent stagnant checkpoint-like developmental states but are persistently progressing

Fig. 1 Histology of the mouse testis—cross-sections of adult seminiferous tubules at different stages of spermatogenesis. During spermatogenesis germ cells at different phases of maturation form cellular associations of constant composition. Twelve (I–XII) associations, or stages of the seminiferous cycle, have been designated for most mammalian species, including man and mouse (shown in figure). For practical purposes stages I–VI, VII–VIII, and IX–XII are often shown as one “pooled” stage. Undifferentiated (A_{undiff}) and differentiating spermatogonia (A_1 to type B) and early meiotic preleptotene spermatocytes dwell on the basal lamina of the seminiferous epithelium. Leptotene to diakinetid (L–D) and secondary spermatocytes plus postmeiotic spermatids do not have a contact to the basal lamina but are engulfed by Sertoli cells and intermingled on the adluminal side of the blood–testis barrier. Peritubular myoid cells and peritubular macrophages encase the seminiferous tubules. Testicular blood vessels run in the interstitium, a home to testosterone-producing Leydig cells, interstitial macrophages, and fibroblasts. The color key used for different cell types is used throughout this article. Micrographs courtesy of Dr. Noora Kotaja.

Fig. 2 Seminiferous epithelial cycle map of mouse spermatogenesis. Stages of the seminiferous epithelium are depicted in the vertical columns (Roman numerals I–XII). The most immature germ cells are placed at the bottom, whereas the most mature are at the top making it a hierarchical map and not necessarily implying to their location within the epithelium. In order to follow the progress of spermatogenesis and gradual development of male germ cells, one has to move from left to right, and from bottom to top. A cycle is a complete series of stages that follow one another in a logical order. Arabic numerals refer to steps of spermatid maturation, that is, spermiogenesis. A_{und} , undifferentiated spermatogonia; A1–4, type A1–A4 spermatogonia; In, intermediate spermatogonia; B, type B spermatogonia; PI, preleptotene spermatocytes; L, leptotene spermatocytes; Z, zygotene spermatocytes; P, pachytene spermatocytes; D, diplotene spermatocytes; 2°, secondary spermatocytes plus meiotic divisions. Drawn by MSc Sheyla Estefani Cisneros-Montalvo.

as different cohorts of germ cells at a specific area synchronously undergo spermatogenic differentiation. Staging of the seminiferous cycle is merely a tool that makes spermatogenesis easier to study, analyze, and comprehend. During the course of one cycle a certain area in the tubule undergoes all the stages. A spermatogenic unit of a Sertoli cell and associated germ cells is like a water molecule in the ocean. Its position in space does not change as a result of the passing spermatogenic wave, but the wave does affect the developmental state of spermatogenic cells within the unit and lifts them one level higher in the differentiation hierarchy (Fig. 2).

The duration of the seminiferous cycle varies between different species and even within a species between the different strains (Russell et al., 1990). The cycle length in man is 16 days, whereas in the mouse it takes only 8.6 days to complete a cycle (Oakberg, 1956; Heller and Clermont, 1963). Approximately four cycles are needed by germ cells to undergo spermatogenesis from a differentiating spermatogonium to a mature elongated spermatid with a flagellum and an acrosome. This brings the duration of spermatogenesis to 74 and 35 days in man and mouse, respectively (Fig. 3A) (Heller and Clermont, 1964; Clermont, 1972). The cycle length and therefore the duration of spermatogenesis are fundamental characteristics of a species. Creation of knock-out animal models and naturally occurring mutations have shown that spermatogenesis can go wrong at many different steps and is not even initiated if undifferentiated spermatogonia fail to commit. However, up to date it has not been reported that in any conditions either due to loss of gene function or adverse environment the seminiferous cycle length would have been altered. However, in rodents the first round of spermatogenesis represents a distinctive program of germ cell differentiation, and it differs from the following ones in many aspects, including the cycle length (Yoshida et al., 2006; Kluin et al., 1982). The reason or the underlying mechanisms for shortening of the cycle in peripubertal rodents are not known. It has been hypothesized that the first cycle is started from fetal gonocytes that would follow a distinct developmental rhythm, whereas all the following cycles start from the spermatogonial stem cell pool.

The Onset and Cycle-Dependent Coordination of Spermatogenesis

In the mouse, spermatogenesis starts when the differentiation-primed subpopulation of type A undifferentiated spermatogonia (A_{undiff}) transition into type A1 differentiating spermatogonia (A_1) at stages VII–VIII of the seminiferous cycle (Fig. 3B). This transition is an irreversible step and A_1 spermatogonia are committed to differentiate into haploid elongated spermatids over the course of 35 days (Clermont, 1972). A_{undiff} become sensitive to differentiation-inducing stimuli (1) by upregulating the expression of retinoic acid receptor gamma (RAR γ), (2) by becoming mitotically quiescent by stage II of the seminiferous epithelial cycle,

Fig. 3 Kinetics of spermatogenesis. (A) Timeline of sperm production in the mouse. Self-renewing undifferentiated spermatogonia transit into type A₁ differentiating spermatogonia upon entering spermatogenesis. Spermatogenic cells undergo the mitotic (gray rectangle), meiotic (green to blue), and spermiogenic (orange and red) phases to give rise to mature spermatids 35 days, or roughly four 8.6-day seminiferous cycles, later. eP-mP-IP, early-mid-late pachytene spermatocytes. (B) Schematic presentation of germ cell maturation at a specific locus in the seminiferous tubule as a function of time. Spermatogenesis starts as A_{undiff} spermatogonia differentiate into A₁ spermatogonia at stages VII–VIII of the seminiferous epithelial cycle. The next generation of differentiating spermatogonia is formed after one cycle of the seminiferous epithelium, that is, 8.6 days later, and spermatids are released after 35 days. Asynchronous onset of spermatogenesis along the length of the seminiferous tubule ensures continuous sperm release. At a specific locus, sperm release is pulsatile (once in 8.6 days). Purple shading on the background depicts cyclic action of Sertoli cells during the spermatogenic cycle. Hierarchically stratified layers of germ cells (A–F as described in Fig. 2) are continually recreated as spermatogenesis proceeds. Abbreviations as described in Figs. 1 and 2.

and (3) by being exposed to differentiation-priming activity of the Wnt/beta-catenin signaling pathway (de Rooij, 2001; Ikami et al., 2015; Takase and Nusse, 2016; Tokue et al., 2017). A_{undiff} are a heterogeneous population of cells, and despite having a capacity to self-renew (stem cells), only a subset of them actually does so, while the majority are destined to differentiate (progenitor cells). Differentiation propensity within the A_{undiff} spermatogonia is associated with increased expression of neurogenin3 (Ngn3) and Sox3 (SRY-box 3), and decreased expression of GFRa1 (GDNF family receptor alpha 1) (Ikami et al., 2015; Raverot et al., 2005). A_{undiff} at stages VII–IX are exposed to the pulsatile secretion of retinoic acid that stimulates expression of Stra8 (stimulated by retinoic acid gene 8), promotes entry into S phase of the cell cycle and induces directly and indirectly the expression of Kit, a hallmark of spermatogonial differentiation commitment, in the differentiation-primed A_{undiff} (Pellegrini et al., 2008; Zhou et al., 2008; Carlomagno et al., 2010; Barrios et al., 2012; Suzuki et al., 2012; Yang et al., 2013; Chen et al., 2016; Hogarth et al., 2015). The expression of DNA methyltransferases 3a and 3b (Dnmt3a/b) plus a number of other genes are also stimulated in the nascent committed spermatogonia (Shirakawa et al., 2013; Evans et al., 2014). Activation of Dnmt3a/b results in modification of the committing germ cell epigenome and is probably responsible for the irreversibility of the event (Shirakawa et al., 2013).

While stem and progenitor spermatogonia divide in an at least somewhat random fashion (restricted to stages X–II, though), the mitoses of differentiating spermatogonia are rigidly timed and bound to the progress of the seminiferous cycle (Fig. 2) (de Rooij and Russell, 2000). A₁ spermatogonia divide at stage IX to produce A₂ spermatogonia. A₃ spermatogonia are derived from mitosis of A₂ at stage XI. A₃ spermatogonia give rise to A₄ at stage I. A₄ spermatogonia divide at stage II to form intermediate spermatogonia (In), which undergo mitosis at stage IV to produce type B spermatogonia. The last mitotic division in the male mouse germ-line takes place at stage VI. The progeny of the division are meiotic preleptotene spermatocytes, and retinoic acid has a vital role in the meiotic entry of germ cells (Anderson et al., 2008). Spermatocytes undergo two meiotic divisions about 1.5 cycles later at stage

XII, and the haploid round spermatids appear at stage I. Their cellular morphology starts to change from round to elongated at stage VIII (step 8) and fully matured step 16 elongated spermatids are disengaged from the epithelium (spermiation) one cycle later. Differentiation of spermatids (spermiogenesis) is an intricate process and takes approximately 1.5 cycles to complete independent of the species. The duration of different stages is known and there is some biological variation in the duration of particular stages among individuals of the same species (Muciaccia et al., 2013). The seminiferous cycle in man differs somewhat from the mouse. Most remarkably, meiotic entry and spermiation take place at earlier stages and the spermatogenic starting point, that is, transition from progenitor to differentiating spermatogonial cell (A_{undiff} to A_1 in the mouse), is not known (Muciaccia et al., 2013).

Thousands of coding and noncoding RNAs are transcribed during the spermatogenic cycle (Laiho et al., 2013). The expression of many of these transcripts is confined to a specific cell type and/or specific stage of the seminiferous cycle. These genes are said to have a stage-dependent pattern of expression. Transillumination-assisted microdissection method has made it possible to analyze stage-specific gene and protein expression in vitro (Toppari and Parvinen, 1985; Parvinen et al., 1986). Many key regulatory factors, such as inhibins and activins (Bhasin et al., 1989; Kaipia et al., 1991, 1992, 1993, 1994), testicular interleukin-1 (Soder et al., 1991) and stem cell factor/Kit-ligand (Yan et al., 1999; Hakovirta et al., 1999) are expressed cyclically, as well as plasminogen activators that are hypothesized to act on structural dynamics of the seminiferous epithelium (Penttilä et al., 1994; Toppari et al., 1986, 1988; Vihko et al., 1987). However, not all regulatory factors are cyclically expressed, for example, GATA 4 and 6 (Ketola et al., 1999).

Coordination of individual steps on the spermatogenic pathway is vital for its successful completion. Meiotic checkpoints ensure genetic integrity of gametes and provide the system with a quality control mechanism, and a way to dispose of the flawed germ cells (Subramanian and Hochwagen, 2014). Apoptosis is no stranger to spermatogenesis and spermatogenic cells can undergo apoptotic cell death at many different phases of differentiation (Huckins, 1978; Allan et al., 1992; Shaha et al., 2010). It is estimated that only one fourth of spermatogonial progeny makes it to mature spermatids (Russell et al., 2002). In spite of massive apoptosis, the spermatogenic machinery of the testis is a highly efficient system and fertile men produce about 100 million sperm per day (Johnson et al., 1980). Synchronous spermatogenesis of different cohorts of germ cells at four hierarchical layers of differentiation (differentiating spermatogonia, spermatocytes, round spermatids, elongating spermatids—not all present at every stage, possibly two different generations present at a particular stage) provides the system with a possibility to coordinate the development of spermatogenic cells at different hierarchical layers of development, and it also saves space (Figs. 2 and 3B). However, it also sets unprecedented requirements for the somatic supporting cells of spermatogenesis, especially the Sertoli cells.

The Sertoli Cell and Regulation of the Seminiferous Epithelial Cycle

Sertoli cells (SCs) are the only somatic cells located within the seminiferous tubules. SCs in the adult are a large highly specialized postmitotic epithelial cell type that spans from the basal lamina of the seminiferous epithelium to the tubular lumen, and as one among its many functions provides a physical scaffold for the developing germ cells (Fig. 1). The main function of SCs is to generate a specialized microenvironment for each stage of the seminiferous cycle that enables germ cells to differentiate, divide, and survive. This does not apply just to a single subpopulation of germ cells but due to presence of up to six different generations of germ cells (including stem and progenitor A_{undiff} spermatogonia) at a particular stage, this is a considerable effort (Figs. 2 and 3B). SCs display unparalleled plasticity in terms of function and gene expression across the cycle of the seminiferous epithelium.

Germ cells do not express receptors for androgens or gonadotropins FSH (follicle-stimulating hormone) or LH (luteinizing hormone), but it is the Sertoli cells that are responsible for transducing endocrine signals and other cellular cues into paracrine regulation of spermatogenesis. FSH and testosterone are the key regulators of spermatogenesis and SCs therefore have a central role in the maintenance of the epithelial cycle. The effect of these two factors on SCs is stage-dependent. The highest levels of androgen receptor (AR) are expressed in stages VI–VII, whereas FSH acts on Sertoli cells most strongly in early stages of the seminiferous epithelial cycle (Zhou et al., 2002; Kangasniemi et al., 1990a). FSH and testosterone regulate the expression of hundreds of genes in Sertoli cells (McLean et al., 2002; De Gendt et al., 2014). Due to disparities in their windows of action (in the late-to-early or mid-to-late stages for FSH and testosterone, respectively) they regulate different aspects of spermatogenesis (Parvinen, 1993). The concerted action of both of them is required for normal spermatogenesis. The Sertoli cell functional cycle not only involves cyclical changes in gene expression but also in cell morphology and biochemical activity (Parvinen, 1993; Morales and Clermont, 1993). The importance of cyclic gene expression in SCs for normal spermatogenesis has been taken as given. This is understandable because a gene that is expressed in Sertoli cells often regulates transcription of other genes in germ cells. Thus stage-dependent gene expression in SCs reflects to stage-dependent expression of a germ cell gene needed to complete a specific step along the differentiation pathway, for instance. Stage-dependent expression of receptors (AR, FSHR, etc.) for ligands that are continually available (testosterone, FSH, etc.) is one of the main mechanisms that is needed for maintenance of the seminiferous cycle. In the absence of gonadotropins, apoptosis starts in pachytene spermatocytes and spermatids at stages VII–VIII (Toppari et al., 1989).

Sertoli cell functional cycle coincides with the seminiferous epithelial cycle. They are not the same thing, however, and the phase of the Sertoli cell cycle is dictated by the stage of seminiferous cycle. In undisrupted testis, due to the intimate relationship of SCs and associated spermatogenic cells, the opposite is equally true and full manifestation of the characteristics of either of the cycles is not possible in the absence of the other. There are three different mechanisms that have been suggested to control the Sertoli cell cycle and therefore the seminiferous epithelial cycle, too: (1) Stage-dependent expression of receptors for ligands that are continually available (such as testosterone and FSH), (2) paracrine and juxtacrine factors whose availability is limited to (a) specific stage(s) (such as retinoic acid as discussed below), and (3) Sertoli cell intrinsic program that drives stage-dependent gene expression

Fig. 4 The regulation of the Sertoli cell cycle. The cyclic function of the Sertoli cell (in the middle, colored blue) is regulated by three different mechanisms: (1) Stage-dependent availability of paracrine and juxtacrine factors produced by spermatogenic cells, (2) Stage-dependent expression of receptors for endocrine and paracrine factors, and (3) Sertoli cell intrinsic program that controls cyclic gene expression independent of germ cells.

independent of germ cells probably via a *Dmrt1*-dependent mechanism (Fig. 4) (Timmons et al., 2002; Matson et al., 2011). Germ cells are not, however, the puppets of SCs and their dictatorial paracrine control mechanisms. Xenotransplantation of germ cells from rat testis to mouse seminiferous tubules recapitulates rat spermatogenesis in an alien environment, and rat spermatogenic cells differentiate according to their intrinsic 12.9-day cycle instead of following the host's seminiferous cycle of 8.6 days (Russell and Brinster, 1996; Franca et al., 1998). The cycle length thus seems to be an inherent property of the germ cells, which just make use and take benefit from the surrounding somatic environment to accomplish their task of spermatogenic differentiation. Moreover, experiments where differentiating spermatogonia were killed with X-irradiation (Kangasniemi et al., 1990b), which resulted in a specific lack of succeeding spermatogenic cells over time, revealed a strong influence of the germ cells on Sertoli cell cyclic function (Kaipia et al., 1990, 1991; Kangasniemi et al., 1990c).

Re-establishment of the spermatogenic wave after allogeneic transplantation takes half a year in the mouse (Ventelä et al., 2002). For the first 2–3 months posttransplantation the colonies derived from single stem cells represent just one stage, even after fusion and having reached the length of >1 cm (Ventelä et al., 2002). Synchronization of the cycle within a colony suggests that the inducer is the transplanted cell and its progeny. Synchronization of germ cell differentiation in the fused colonies is an unexpected finding and the mechanism responsible for cycle shift in one or more of the merging colonies is not known. In these colonies, spermatogenic differentiation only takes place in the middle parts and spermatogonial proliferation is seen in the periphery. It might be that lack of a barrier function elicited by differentiating germ cells allows diffusion of a stage-synchronizing factor to neighboring regions along the seminiferous tubule resulting thus in the observed outcome. Spermatogenesis would need to be reinstated over a specific threshold for this barrier to be established and this would take about 6 months in the discussed context.

While pieces of data suggest that germ cells have superior control on the seminiferous epithelial cycle over Sertoli cells, SCs display at least some aspects of their cyclic function in testis devoid of germ cells: in a congenitally germ cell deficient testis, in case of a block in spermatogenic entry due to vitamin A or RA signaling deficiency, or after germ cell depletion (Timmons et al., 2002; Sugimoto et al., 2012). Developmental heterogeneity is first observed in testicular somatic cells and a report suggests that the seminiferous epithelial cycle is prefigured in SCs during fetal development, latest mouse embryonic day 18 (Timmons et al., 2002). The data from xenogeneic transplantation studies nonetheless indicate that germ cells are capable of overriding the SC intrinsic clock and adjust it according to their own needs (Franca et al., 1998; Clouthier et al., 1996; Ogawa et al., 1999a,b). The molecular mechanisms responsible for resetting the SC clock have yet to be fully uncovered but it is obvious that paracrine and juxtacrine signaling is involved. There is one potent factor, though, that might have a crucial role in the process—retinoic acid.

The Onset and Maintenance of the Seminiferous Cycle—The Role of Retinoic Acid

Retinoic acid is a potent short-lived lipophilic paracrine and autocrine factor. In the testis it is synthesized from blood-borne retinol (fat-soluble dietary vitamin A) by the action of retinol and retinaldehyde dehydrogenases (RDH, RALDH), and actively degraded by CYP26 (cytochrome P450 family 26) enzymes (Rhinn and Dolle, 2012). The levels and distribution of RA in the testis are tightly controlled. Besides degradation, the bioavailable levels of RA can be regulated by storage of retinol in lipid droplets after esterification (Chung and Wolgemuth, 2004). Circulating retinol is bound to a carrier protein.

There are three receptors (RARα, RARβ, and RARγ) that bind RA. They form heterodimeric complexes with retinoid X receptors (RXRα, RXRβ, RXRγ). Interestingly, at many genomic loci the nuclear function of RAR/RXR heterodimer depends on ligand availability. Upon ligand binding the complex associates with co-activator proteins and stimulates transcription of RA responsive genes, whereas if the ligand is not available, RAR/RXR heterodimers adopts a conformation that enables interaction with co-repressors and results in downregulation of RA responsive gene expression (Rhinn and Dolle, 2012).

The data supporting the role for RA in the induction and maintenance of the seminiferous epithelial cycle is solid. Despite recent advances in understanding the role of RA in molecular detail, the crucial importance of RA for spermatogenesis has been known for nearly a century (Wolbach and Howe, 1925). Loss of RA signaling due to vitamin A deficiency, for instance, leads to azoospermia due to a block in the spermatogenic entry and accumulation of A_{undiff} spermatogonia. Administration of RA or its precursors restores the seminiferous epithelial cycle and spermatogenesis (Morales and Griswold, 1987; van Pelt and de Rooij, 1990). RA availability

needs to be tightly regulated developmentally and during steady state spermatogenesis as ectopic RA would result in premature meiotic entry both in prepubertal testis and during spermatogenesis (Sugimoto et al., 2012; MacLean et al., 2007). Differentiation-primed A_{undiff} spermatogonia at stages II–VIII are sensitive to RA stimulus but the transition into A_1 only takes place at stages VII–VIII (Hogarth et al., 2015). Testis must therefore actively employ mechanisms that limit bioavailability of RA at stages II–VI. The highest RA levels are recorded at stages VIII–IX but RA stays at a relatively high concentration throughout stages VII–XII (Hogarth et al., 2015; Sugimoto et al., 2012; Hasegawa and Saga, 2012). Due to short half-life of RA, it is likely that RA is actively produced at these stages, while only residual levels of RA are measured at stages I–VI. This stage VII–IX specific RA pulse coincides with induction of Stra8 expression in A_1 spermatogonia and preleptotene spermatocytes and beginning of Kit expression in A_1 spermatogonia, which is considered a hallmark of spermatogonial differentiation commitment (Pellegrini et al., 2008; Zhou et al., 2008). Retinoic acid has also been shown to affect gene expression in seminiferous epithelium in a stage-specific manner in vitro (Vihko et al., 1987; Toppari et al., 1986).

Sertoli cell-derived RA is needed for the efficient initiation of the first cycle of the seminiferous epithelium in the prepubertal rodent (Raverdeau et al., 2012; Tong et al., 2013). However, the subsequent cycles may partly or fully depend on RA from alternative sources. The most likely candidates would be the preleptotene spermatocytes that appear one cycle (8.6 days) later, or late, stage VII–VIII, pachytene spermatocytes (Raverdeau et al., 2012; Davis et al., 2013; Vernet et al., 2006a; DeFalco et al., 2015). Both these cell types strongly express proteins that are needed for RA synthesis (Raverdeau et al., 2012; DeFalco et al., 2015; Vernet et al., 2006b). Round spermatids of stages II–VI limit availability of retinol for RA synthesis by expressing genes that are needed for its esterification and storage (Sugimoto et al., 2012; Vernet et al., 2006b). However, postmeiotic germ cells might also produce RA or its precursors (DeFalco et al., 2015; Vernet et al., 2006b). Interestingly, late round spermatids and elongating spermatids express *Bcmo1* (beta-carotene oxygenase 1), a gene needed to produce RA precursor retinaldehyde from beta-carotene (Vernet et al., 2006b). Additionally, testicular macrophages have been suggested to play a role in testicular RA metabolism and creation of spermatogonial niche, and the RA producing machinery is also present in Leydig cells (DeFalco et al., 2015; Vernet et al., 2006b). The significance of Leydig cell and macrophage-derived RA for spermatogenesis can be justifiably questioned because peritubular myoid cells, which encase the seminiferous tubules, strongly express Cyp26 isoforms, the enzymes needed for RA degradation (MacLean et al., 2007; Vernet et al., 2006b). One of the functions of peritubular myoid cells would therefore be the degradation of extratubular RA originating from the interstitium, vasculature or neighboring tubules. The patchy location of a subset of testicular macrophages at the peritubulus might still enable these cells to play role in the intratubular RA metabolism (DeFalco et al., 2015).

Based on the available data (see above), the following model for the role of RA in the initiation and maintenance of the seminiferous cycle is proposed (Fig. 5): RA is actively degraded in the embryonic testis. In prepubertal rodents, Sertoli cell-derived RA induces the onset of the first round of spermatogenesis along the whole length of the seminiferous tubule in a temporally controlled manner, and as a result a subset of nascent spermatogonia transition into differentiating spermatogonia. The subsequent cycles depend on RA produced by differentiating germ cells and acts on differentiation-primed A_{undiff} spermatogonia. In the adult, preleptotene spermatocytes appearing once during every cycle, after 8.6-day intervals, and late pachytene spermatocytes synthesize and secrete RA at stages VII–IX of the seminiferous cycle. RAR γ expressed by the spermatogonial progenitor cells respond to this RA pulse and commit to differentiate. The progeny of these cells then takes part in producing the next pulse in 8.6 days and so on. This mechanism would be the basis of seminiferous epithelial cycle and Sertoli cell functional cycle and reset the Sertoli cell “clock” to stage VII once during every cycle. Esterification and storage of RA precursors by early step 2–6 round spermatids (at stages II–VI) would limit the availability of RA and prevent premature A_{undiff} to A_1 transition and untimely meiotic entry of differentiating spermatogonia.

RA signaling is not vitally important only for the onset and maintenance of spermatogenesis and the seminiferous epithelial cycle but also for the Sertoli cells. Lack of RAR α in SCs results in uniform expression of stage-dependent transcripts in adult SCs, which suggests that RA signaling regulates the SC cyclic gene expression and therefore the Sertoli cell cycle (Fig. 5). However, ablation of RAR α in SCs does not immediately abolish the seminiferous cycle, and the data suggest that the seminiferous epithelial cycle can proceed even after loss of SC cyclicity (Vernet et al., 2006a). This raises two questions: for how long and at what cost? Indeed, SC specific deficiency of RAR α results primarily in spermatogenic defects and ultimately in SC only phenotype where seminiferous tubules are devoid of germ cells. These data provide another piece of evidence for the interdependency of the seminiferous and Sertoli cell cycle.

The Origin of the Seminiferous Cycle and Its Spatially Asynchronous Onset

The RA-induced transition of differentiation-primed A_{undiff} to A_1 spermatogonia at stages VII–VIII sets the stage for male germ cell differentiation. Its spatio-temporally asynchronous implementation along the length of the seminiferous tubule ensures continual supply of sperm and guarantees that mature elongated spermatids are always available for release from a specific proportion of seminiferous epithelial surface (Fig. 3B). Were it not asynchronous, sperm would be released in a pulsatile manner, that is, every 16th day in man, for instance. It is obvious that this would greatly reduce the capacity of a male to fertilize an oocyte. Conversely, in species where sperm is released just once per a reproductive season (many species of fish, e.g.) synchronous spermatogenesis is a viable reproductive strategy (Billard, 1986).

In the mouse and rat, the seminiferous cycle can be synchronized in time and space. This happens after injection of RA or its precursor into animals that have been on a vitamin A deficient diet, or to early neonatal mice, and results in loss of spermatogenic

Fig. 5 A model for the role of RA in the induction and maintenance of the seminiferous cycle. (A) In the developing embryo, testicular somatic cells strongly express CYP26 enzymes that degrade RA in order to prevent premature meiotic entry of the gonocytes (*round gray cells*). Unidentified factors (*question marks*) act on Sertoli cells to prefigure the seminiferous epithelial cycle in the SC epigenome. (B) RA production is induced in prepubertal Sertoli cells in a patch-like fashion. Blood-borne retinol (ROH) is converted first into retinaldehyde (RAL) by retinol dehydrogenase (RDH), and then into RA by RALDH (retinaldehyde dehydrogenase). Spatio-temporally controlled synthesis and release of RA results in an asynchronous spermatogenic entry of gonocyte-derived nascent spermatogonia (*round gray cells*). RA does not affect all germ cells but some are unresponsive to RA and form the spermatogonial stem cell pool (*flattened gray cells*). (C) Round spermatids of stages II–VI express LRAT (lecithin-retinol acyltransferase) and ADFP (adipose differentiation related protein) whose action leads to esterification and storage of retinol and consequent low RA synthesis and availability. This mechanism prevents the untimely spermatogenic entry of stage II–VI undifferentiated spermatogonia. (D) At stage VII–VIII late pachytene spermatocytes express proteins that are needed for RA synthesis (RDH and RALDH). RA induces meiotic entry of type B spermatogonia/preleptotene spermatocytes that also produce RA. RA derived from these sources (so called RA pulse) forces differentiation-primed A_{undiff} spermatogonia (*flattened gray cells*) to commit and also affects Sertoli cell cyclic function. Appearance of a new generation of RA producing cells in 8.6 days is the key mechanism that drives and coordinates the cycle of the seminiferous epithelium. Peritubular myoid cells strongly express CYP26 and degrade RA derived from Leydig cells, interstitial macrophages, circulation, and neighboring seminiferous tubules.

wave due to synchronous differentiation of germ cells along the whole length of the seminiferous tubule and existence of just a few stages at a given time (Morales and Griswold, 1987; van Pelt and de Rooij, 1990; Davis et al., 2013). As discussed above, this happens because unavailability of RA leads to accumulation of stem and differentiation-primed A_{undiff} spermatogonia, and a sudden burst of RA results in synchronous spermatogenic entry at all locations along the tubule and near simultaneous completion of spermatogenesis, and pulse-like release of sperm that is repeated in every 8.6 and 12.9 days in mouse and rat, respectively (Morales and Griswold, 1987; van Pelt and de Rooij, 1990). The synchronizing effect of RA on spermatogenesis depends on pretreatment availability of endogenous RA (Hogarth et al., 2015; Sugimoto et al., 2012; Davis et al., 2013). If the testis has never experienced normal cyclical RA, the cycle can be permanently synchronized (Hogarth et al., 2015; Davis et al., 2013). However, the seminiferous epithelial cycle is progressively desynchronized if spermatogenesis had started in the treated animals (Bartlett et al., 1990).

The ultimate trigger for asynchronous spermatogenesis and entry of nascent spermatogonia into the first cycle of seminiferous epithelium and consequent first round of spermatogenesis is yet to be identified. The earliest signs of asynchronous germ cell development are observed during early postnatal life as on postnatal day 2–3 RA signaling is activated in a patch-like fashion in a subset of nascent spermatogonia (Fig. 5B) (Snyder et al., 2010, 2011). This does not provide an answer about the nature of inducing factor and how does it mechanistically contribute to the asynchronous onset of spermatogenesis, though, but merely suggests that it is probably of fetal or embryonic descent. The cellular origin of the inducing signal has not been demonstrated,

but SCs are the most likely candidate due to early heterogeneity within this cell population (Fig. 5A) (Timmons et al., 2002). It is also possible, however, that a subset of gonocytes is set aside early on during prenatal development and it is these cells that enter spermatogenesis in the prepubertal rodent. One thing is evident, however, that is, the need for more research on the developmental origin of the seminiferous epithelial cycle.

The Sertoli Cell “Clock”

The conclusion from a bulk of data discussed above is that cyclic gene and protein expression and function of adult-type Sertoli cell is regulated by “a clock” and retinoic acid sets the clock but differentiating meiotic and postmeiotic germ cells are needed for its fine-tuning. The idea of differentiating germ cells having an effect on Sertoli cell cyclic function is not a new one but its molecular identity has awaited validation (Parvinen, 1993; de Rooij et al., 1985; Kaipia et al., 1991). What is then the nature of the Sertoli cell “clock” and the pace maker of the seminiferous epithelial cycle (Fig. 6)? Ability of RA to reset the Sertoli cell cycle provides a hint as to how the cyclic function of SCs and the seminiferous cycle are controlled. There might be other spermatogenic cell-derived paracrine factors in addition to RA that fine-tune the function of SCs and contribute to its characteristic seminiferous cycle dependency. SCs would only be required for the onset of the seminiferous epithelial cycle and thereafter the gradual appearance of more advanced populations of spermatogenic cells would be in charge of keeping the spermatogenic process and the seminiferous cycle going. In this model the seminiferous cycle-inducing capacity of Sertoli cells via secretion of RA would not be lost upon SC maturation because transplantation and consequent repopulation of the seminiferous epithelium would not take place in the absence of it. These considerations would make the spermatogenic program encoded into germ cell genomes the pace maker of spermatogenesis and the ultimate controller of Sertoli cell functional cycle, and would leave SCs a role in the initiation of the seminiferous epithelial cycle during the first (and second) round of spermatogenesis and later in life if needed. However, after allogeneic transplantation the cell density of A_{undiff} might also play a role and the differentiation-inducing stimulus (RA) might arise from the A_{undiff} population itself when sufficient cell density is reached (Ventelä et al., 2002). Identification and characterization of significant seminiferous epithelial cycle modifiers or those that are able to reset the cycle in a RA manner (unlikely to exist) are yet to be achieved.

The availability of data showing the significance of RA for human spermatogenesis is limited but surprisingly it may not have an equally central role in primates as in rodents. Long-term administration of RA synthesis inhibitors results in near or complete absence of sperm suggesting that RA signaling is vital for human spermatogenesis, as well (Heller et al., 1963). However, there were defects only in postmeiotic germ cell differentiation but the treatment had no effect on spermatogonia and spermatocytes. Just a glimpse at the stage map of human spermatogenesis suggests that a similar hot spot of cell fate decisions as stage VII–VIII is in rodents (A_{undiff} to A_1 , meiotic entry, start of spermatid elongation and release of matured spermatids), does not exist in man (Muciaccia et al., 2013). Either the RA pulse in man is multiphasic, which is unlikely, or RA has a somewhat different role in human spermatogenesis. Further studies about the role of RA in human spermatogenesis are in high demand.

Fig. 6 The Sertoli cell clock. During the course of the seminiferous cycle, the Sertoli cell is exposed to varying environment and phase of the Sertoli cell clock (I–XII) is determined by paracrine and endocrine factors, composition of the interacting germ cell population and the intrinsic Sertoli cell cycle. Untimely and ectopic availability of an adjusting agent, or lack of it, will affect the Sertoli cell clock and depending on the identity and intensity of the signal may reset (like RA) or adjust it. Size of the icon (FSHR, AR, RA) corresponds to the abundance of the specific molecule.

Glossary

Disengagement complex An integrin-based adhesion junction that mediates the final release of sperm from the Sertoli cell.

Ectoplasmic specialization A Sertoli cell-derived actin-based adhesion junction that enables developing spermatids to adhere to Sertoli cells as they elongate.

Seminiferous epithelium The epithelium within the seminiferous tubules of the testis: it is comprised of the Sertoli cells and germ cells at different stages of development.

Sertoli cell A large complex somatic cell that is required for male germ cell development and sperm production.

Spermatogenesis The entire process by which immature precursor male germ cells develop into spermatozoa within the seminiferous tubules.

Spermiogenesis The maturational process by which round spermatids transform into spermatozoa.

Tubulobulbar complex A novel endocytic-type machinery present in Sertoli cells: it consists of an actin-associated tubule portion terminating in a bulbous vesicle portion that can bud off to become an endocytic vesicle.

Introduction

Spermiation is the process by which elongated spermatids, at the end of spermatogenesis, undergo their final remodeling and are released in the lumen of the seminiferous tubules prior to their passage to the epididymis. This process is long, taking more than 80 h in rats (O'Donnell et al., 2011), and is multi-faceted, involving various cytoskeletal structures within the adjacent Sertoli cells. The goal of spermiation is to release the mature spermatid from the Sertoli cell, however this process also involves remodeling of the spermatid to produce a streamlined spermatozoon.

The morphological and ultrastructural events associated with spermiation are well described and are conserved across mammalian species including rodents and humans (O'Donnell et al., 2011; Russell, 1993). The molecular regulation of spermiation is less well understood but involves signaling and adhesion molecules (Chapin et al., 2001) as well as the regulation of unique cytoskeletal structures.

Spermiation is an important determinant of sperm content in the ejaculate. Spermiation is vulnerable to various insults including hormone suppression and toxicant exposure, and the failure of sperm release can have a major impact on testicular sperm output (O'Donnell et al., 2011; Russell, 1991).

Initiation of Spermiation

Prior to spermiation, elongated spermatids have an extensive cytoplasm located around the flagellum (Figs. 1 and 2). The spermatid nuclei are located deeper within crypts between Sertoli cells (O'Donnell et al., 2011; Russell, 1993) and associate with the Sertoli cells via a unique actin-associated adhesion junction called the ectoplasmic specialization, or ES (Vogl et al., 2000). This is a Sertoli cell adhesion junctional structure that forms opposite spermatids as they commenced elongation some weeks prior, and it confers tight adhesion between these cells as the spermatids proceed through the elongation phase of spermiogenesis. Spermiation begins when the elongated spermatid nuclei are rapidly translocated to the luminal edge of the epithelium (Figs. 1 and 2); this upwards translocation is facilitated by the ES associating with motor proteins that move along tracks of microtubules within Sertoli cells (Guttman et al., 2000).

At the beginning of spermiation, the extensive spermatid cytoplasm projects out into the tubule lumen, but the spermatid remains tightly associated with the Sertoli cell via an extensive ES structure that surrounds the spermatid nucleus, see Fig. 2 and (Russell, 1993). The successful release of sperm necessitates the removal of this complex. To accomplish this, a testis-specific structure called the Tubulobulbar Complex (TBC) forms between the Sertoli cell and the spermatid (Figs. 2 and 3, reviewed in Vogl et al., 2014). TBCs are a modified form of clathrin-based endocytic machinery. These first form in the plasma membrane of the Sertoli cell in regions of ES disassembly, first appearing as a coated pit on the cytoplasmic side of the Sertoli cell plasma membrane (Fig. 3). This coated pit elongates into a tubular structure, facilitated by the polymerization of dendritic actin filaments, terminating in a bulbous region surrounded by endoplasmic reticulum (Vogl et al., 2014). The mature TBCs are comprised of both spermatid and Sertoli cell plasma membranes (Fig. 3). Once TBCs are fully formed, the bulbous region buds off to become an endocytic vesicle which is then processed by the Sertoli cell. Therefore TBCs are large endocytic structures that likely internalize extensive regions of

Fig. 1 Light microscopy of the progression of spermiation in the rat. The stages of the spermatogenic cycle are indicated along the top of the micrographs. The elongated spermatid nucleus is indicated by black arrows, whereas white arrows indicate the developing round spermatids in the epithelium below. The white asterisk indicates the condensing cytoplasm of the spermatid as it is gradually removed by the Sertoli cell. Spermiation commences at the beginning of stage VII in rats and mice, as the spermatid nuclei line up along the luminal edge. Spermiation ends with the disengagement of sperm towards the end of stage VIII, with the whole process taking ~80 h to complete. Figure modified from O'Donnell et al. (2011).

Fig. 2 Diagram of the major processes involved in spermiation. The diagram is based on rat spermatogenesis and is modified from O'Donnell et al. (2011). The diagram summarizes various morphological and ultrastructural events as described in Russell (1993). Note the relationship of the spermatid nucleus with the luminal edge of the seminiferous epithelium (indicated by the *dashed line*), as well as the changes in the shape of the Sertoli cell cytoplasm (*white*) around the spermatid and the remodeling of the spermatid cytoplasm (*gray*). The diagram summarizes how the spermatid nucleus is gradually extended out into the tubule lumen by the elongation of the Sertoli cell cytoplasmic stalk, and how the spermatid cytoplasm remains anchored to the Sertoli cell and is gradually stripped off as the spermatid is extended further into the lumen.

both Sertoli cell and spermatid plasma membranes, together with their associated proteins. The functions of TBCs will be further discussed below, however the fact that components of the ES and adhesion molecules are present within TBCs, highlights their role in ES removal and the remodeling of adhesion junctions (Vogl et al., 2014; O'Donnell et al., 2011; Upadhyay et al., 2012).

Another event that occurs at the beginning of spermiation is the clustering of integrin molecules along the outside curvature of the spermatid nucleus (Beardsley et al., 2006; O'Donnell et al., 2011). This clustering could be triggered by the spermatid being

Fig. 3 Diagram of the Tubulobulbar complexes (TBCs) forming in the ventral curvature of the spermatid nucleus, in sites of the Sertoli cell deficient in ectoplasmic specialization (ES). The diagram has been modified from O'Donnell et al. (2011). The TBCs first form as a small clathrin-coated pit (clathrin indicated in red) and then elongate into a mature tubular structure with a round bulbous structure towards one end; this bulbous structure is surrounded by endoplasmic reticulum (indicated in yellow). The maturation of the TBCs appears to be facilitated by the polymerization of dendritic actin (indicated in green). This bulbous structure eventually buds off to form endocytic vesicles in the apical Sertoli cell cytoplasm. The spermatid cytoplasm is indicated in blue shading; note that some of the cytoplasm could potentially flow down towards TBCs and be present within them, as described by Russell (Russell, 1993).

subjected to shear forces from the flow of seminiferous tubule fluid through the lumen, necessitating the formation of an extremely tight adhesion junction that is capable of “holding on” to the spermatid nucleus as it is extended out into the lumen (O'Donnell et al., 2011). This integrin-based junction is likely a focal adhesion type junction (Beardsley et al., 2006, O'Donnell et al., 2011).

The Progression of Spermiation

Once spermiation is initiated, the spermatid and its associated adhesion junctions with the Sertoli cell undergo extensive remodeling over many hours. The entire process takes more than 80 h in the rat (O'Donnell et al., 2011), but is shorter in the mouse: likely around 40 h, based on the duration of the spermiation stages (Russell et al., 1990). Throughout the entire spermiation process, $\alpha 6 \beta 1$ integrins cluster along the Sertoli cell membrane opposite the outer curvature of the spermatid nucleus where it contacts the Sertoli cell, presumably allowing the Sertoli cell to tightly grip the spermatid as the ES is removed (Beardsley et al., 2006). The ligand on the spermatid that binds to Sertoli cell $\alpha 6 \beta 1$ integrin is likely composed of several laminin chains (Yan and Cheng, 2006).

As spermiation proceeds, the volume of the spermatid cytoplasm is greatly reduced, around 50% in rats (Russell, 1993). TBCs may facilitate cytoplasmic reduction by enveloping portions of spermatid cytoplasm and filtering out organelles, allowing a gradual reduction in the volume of the cytoplasm, see Figs. 1, 2 and 3 and O'Donnell et al. (2011), Russell (1993), Upadhyay et al. (2012). As the spermatid cytoplasm reduces in volume, it appears to gradually flow downwards, appearing around the spermatid nucleus where it is termed the cytoplasmic lobe (Figs. 1 and 2). In fact, the cytoplasm itself does not move but instead remains anchored to the Sertoli cell while the apical portion of the Sertoli cell, called the Sertoli cell stalk, extends and gradually pushes the spermatid

head out into the lumen (see Fig. 2). In this way, the Sertoli cell essentially “strips off” the spermatid’s cytoplasm to reveal its streamlined form. This process is obviously important, as any remaining cytoplasm would impede sperm morphology and motility. While the Sertoli cell appears to be responsible for removing the spermatid cytoplasm, there are circumstances where an abnormality within the spermatid itself, such as genetic defects that impact on the structure of the spermatid cytoplasm, prevent the Sertoli cell from successfully removing the cytoplasm (O’Donnell et al., 2011). Such abnormalities are usually associated with impaired sperm release and/or impaired sperm motility as well as infertility (O’Donnell et al., 2011).

During the long process of spermiation, there is extensive remodeling of adhesion junctions and multiple generations of TBCs form, mature and are dissolved. At this time, the Sertoli cell cytoplasm surrounding the spermatid nucleus is rich in endoplasmic reticulum (ER), which changes as spermiation progresses. In the early stages of spermiation, the Sertoli cell apical process surrounding the spermatid head contains so-called flattened ER which transitions into a tubular arrangement as spermiation proceeds (Clermont et al., 1980). Some of this ER associates with the bulbar portion of the TBCs and with the ES as it is dismantled. The ER at this site seems likely to be involved in the active remodeling of adhesion junctions and of TBC formation and dissolution.

Many adhesion, cytoskeletal and signaling proteins are present at the site of the spermiation and undergo changes in localization over the course of the entire process, highlighting the fact that there are marked changes in adhesion junction composition during spermiation (O’Donnell et al., 2011; Chapin et al., 2001). As discussed earlier, the ES is the major adhesion junction between spermatids and Sertoli cells at the beginning of spermiation, however this structure is gradually removed as spermiation progresses. The timing of ES removal appears to vary between species, as in the opossum the ES is lost very soon after the initiation of spermiation, whereas in the rat and mouse ES removal is more gradual (Russell, 1993). Small portions of ES appear to be dismantled at focal sites, followed by the appearance of a coated pit that will form into a mature TBC (Fig. 3) (Russell, 1993); this observation suggests that focal sites of ES disassembly are required for the initial formation of TBCs. However, TBCs appear to be responsible for much of the ES removal that subsequently occurs, as various ES-associated molecules are found within TBCs, and the appearance of TBC correlates with ES loss (Vogl et al., 2014; Vogl et al., 2013). Additionally, the observation of fragments of Sertoli cell and spermatid plasma membranes within TBCs confirms their role in adhesion junction removal (Vogl et al., 2013). Interestingly, early electron microscopy studies suggested that ES structures could be recycled away from the spermatid and translocated downwards to face the newly elongating spermatids below (Russell, 1993) and some observations suggest that TBCs could be involved in this recycling via long-loop recycling endosomes (Vogl et al., 2013).

Late Spermiation

Towards the end of spermiation but prior to spermatid release, the elongated spermatids are at the very edge of the lumen, only remaining in contact with a small proportion of the Sertoli cell cytoplasm (Figs. 1 and 2). The Sertoli cell stalk extends the spermatid out into the lumen while the spermatid’s cytoplasm is now concentrated and situated below the level of the spermatid’s nucleus (Figs. 1 and 2). At the same time, the round spermatids below have just begun the process of elongation, with their nuclei polarized to one side and oriented towards the base of the epithelium (see Fig. 1), and an extensive newly-formed Sertoli cell ES can be seen opposite their acrosomes (Beardsley et al., 2006).

At this point in spermiation, which corresponds to late stage VIII in the rodent, the traditional Sertoli cell ES is not seen in association with the elongated spermatid nucleus (Beardsley et al., 2006; O’Donnell et al., 2011) and therefore is no longer likely involved in spermatid-Sertoli cell adhesion. Instead, a focal-adhesion type junction containing $\alpha 6 \beta 1$ -integrin and a phosphorylated form of Focal Adhesion Kinase (FAK) remains concentrated at the remaining portion of the Sertoli cell that adheres to the spermatid (Beardsley et al., 2006; O’Donnell et al., 2011). This adhesion complex, termed the disengagement complex, appears to form at the beginning of spermiation and persists throughout ES removal (O’Donnell et al., 2011), and likely adheres to the spermatid via specific surface laminins (Yan and Cheng, 2006). TBCs are also still observed at this time, however some observations suggest their morphology may change somewhat, and in particular they often lack the bulbous portion (Russell, 1993). This could suggest that the TBCs at this stage are no longer removing junction components; perhaps instead these “remnant” TBCs could facilitate anchorage of the spermatid to the Sertoli cell (Russell, 1993).

The term “spermiation machinery” is a term used to encompass all of the adhesion and related structures (including TBCs and the ES) that are present between the spermatid and the Sertoli cell during spermiation (O’Donnell et al., 2011). The spermiation machinery is highly dynamic as spermiation progresses (O’Donnell et al., 2011) and facilitates a major redistribution and probably recycling of adhesion and signaling proteins as the spermatid-Sertoli cell junctions are remodeled prior to sperm release (Chapin et al., 2001; O’Donnell et al., 2011). TBCs are an important part of this machinery, removing a variety of adhesion and ES-associated proteins (Vogl et al., 2013). Adhesion-related signaling proteins can be seen in focal “dots” within the Sertoli cell cytoplasm as they are presumably relocated from the Sertoli cell-spermatid interface (Beardsley and O’Donnell, 2003; Chapin et al., 2001). The final disengagement complex that remains likely includes non-bundled actin, various signaling proteins and kinases, as well as integrins and associated cytoskeletal molecules (O’Donnell et al., 2011).

Also at this time, the spermatid cytoplasm has condensed into what will become known as the residual body when the sperm is released. This cytoplasm is now highly condensed and contains various organelles (see Fig. 1), and remains attached to the spermatid by a long cytoplasmic stalk (Fig. 2; O’Donnell et al., 2011).

Disengagement

The final moment of spermiation occurs when the spermatids are released into the tubule lumen; after their release, the spermatids are now referred to as sperm or spermatozoa. This release process is termed disengagement, as the sperm appear to rapidly disengage from the Sertoli cell in an apparent instantaneous loss-of-adhesion event (Russell, 1993). In fact, disengagement is so rapid that it has been rarely observed in histological sections (Russell, 1993). All spermatids in one part of the epithelium are released simultaneously and are rapidly swept away in the tubule fluid towards the rete testis and epididymis, likely propelled by actin-based contractility of the myoid cells surrounding the tubule (O'Donnell et al., 2011; Russell, 1993). In sections of normal testis, released sperm are rarely observed in the lumen of the tubule, as they are swiftly transported to the rete testis. Because of the arrangement of the spermatogenic cycle in “waves” in the seminiferous tubules, the disengagement of sperm occurs in pulses along the length of the tubules, allowing sperm to be constantly produced.

The signaling mechanism that causes the actual disengagement of spermatids from Sertoli cells is not defined, but it seems clear that the Sertoli cell determines when to release the sperm (O'Donnell et al., 2011, Russell, 1993). In vitro models of spermiation have revealed that disengagement can be inhibited by various pharmacological agents including inhibition of integrin function and protein phosphorylation (Chapin et al., 2001; O'Donnell et al., 2011). It is generally considered that coordinated signals within Sertoli cells promote the disengagement complex to release the sperm, as the spermatids are rather inert at this stage due to their lack of cytoplasm (O'Donnell et al., 2011; Russell, 1991). However, the triggers for these signals, and how all Sertoli cells in the same area of tubule release sperm at a similar time, remains unknown. The loss-of-adhesion event is likely associated with changes in adhesive status of the $\alpha 6 \beta 1$ -integrins within the disengagement complex (Chapin et al., 2001, O'Donnell et al., 2011); this could be likened to the integrin-mediated loss-of-adhesion events that occur as cells migrate along extracellular matrix (O'Donnell et al., 2011).

As the sperm are released, the cytoplasmic stalk attaching the spermatid to its cytoplasm stretches and breaks and the subsequent residual body remains anchored to the Sertoli cell (O'Donnell et al., 2011, Russell, 1993). Very soon after, the Sertoli cell completely envelopes and phagocytoses the residual bodies. These large circular vesicles contain various remnant structures, vacuoles, lipid droplets, condensed mitochondria and likely a multitude of proteins, surrounded by the spermatid plasma membrane and by the Sertoli cell plasma membrane (Morales and Clermont, 1993). The residual bodies are then rapidly transported towards the base of the seminiferous epithelium. During migration, they fuse with secondary lysosomes within the Sertoli cell cytoplasm and are transformed and ultimately phagocytosed by the Sertoli cell (Morales and Clermont, 1993). Residual bodies can modulate Sertoli cell functions and could therefore could regulate aspects of spermatogenesis such as blood-testis-barrier function, see (O'Donnell et al., 2011). Intriguingly, recent studies suggest that lipid-like particles derived from residual bodies could be eliminated into the interstitial space (Xiao et al., 2017). Even more intriguingly, the elimination of sperm-specific proteins into the interstitium via residual bodies has been suggested to promote peripheral tolerance of the immune system (Tung et al., 2017). Thus residual bodies may be a way of consistently delivering sperm proteins, which would otherwise be recognized as foreign by the immune system, to immune cells within the interstitium to actively promote immune system tolerance to sperm (Tung et al., 2017).

Spermiation Failure

Spermiation is highly vulnerable to disruption. Defects in the spermiation process can be seen in response to many different pharmacological agents and reproductive toxicants as well as in various transgenic mouse models (O'Donnell, 2014; O'Donnell et al., 2011; Russell, 1993; Russell, 1991). Disruptions to spermiation are often an early feature of spermatogenic damage: the failure of sperm to be released often precedes other morphological abnormalities in spermatogenesis. Given that spermiation is largely controlled by the Sertoli cell, it seems reasonable to assume that many pharmacological agents and toxicants target Sertoli cell signaling that in turn inhibits sperm release. Spermiation failure is often a sign that “all is not well” (Russell, 1993, Russell, 1991) leading to the hypothesis that Sertoli cells could prevent sperm release, and thus restrict fertility, when the environmental conditions are unfavorable (O'Donnell et al., 2011).

The inherent vulnerability of spermiation is likely due to the fact that it is a multistep process, involving many different adhesion, cytoskeletal and signaling molecules as well as formation of endocytic structures: the disruption of any one of proteins involved in these events could conceivably impact on spermiation. It is also important to note that spermiation fails at multiple steps, depending on when the process is disrupted. For example, spermatids can fail to commence spermiation, and instead of being translocated to the luminal edge via microtubule-based motors, remain within the Sertoli cells where they are phagocytosed (O'Donnell, 2014; O'Donnell et al., 2011). Spermatids can be prematurely released before their cytoplasm has been properly removed, or they can fail to disengage at the very end of spermiation (O'Donnell, 2014, O'Donnell et al., 2011).

Spermiation is clearly responsive to hormones. Spermatogenesis is regulated by androgens, produced locally within the testis in response to pituitary LH stimulation, and by FSH released by the pituitary, and both hormones have independent, additive and synergistic effects on testicular sperm production (O'Donnell et al., 2017). Spermiation is impaired by the suppression of androgen and/or FSH (O'Donnell et al., 2011), and by elevated estradiol (Kumar et al., 2015 and references therein). Failure of the final disengagement of spermatids is seen in rodents, monkeys and men after androgen and/or FSH suppression, highlighting that this final loss-of-adhesion event is regulated by endocrine signals targeting the Sertoli cells (O'Donnell, 2014, O'Donnell et al., 2011). Retinoic acid signaling, which regulates multiple aspects of spermatogenesis (O'Donnell et al., 2017), is also required for normal spermiation, reviewed in (O'Donnell et al., 2011).

Because sperm release from the testis ultimately influences the sperm output from the testis, spermiation failure can contribute to reduced sperm numbers in the ejaculate. Thus the success of spermiation is an important determinant of male fertility. This is best characterized in models of hormone-based male contraception, where androgen and FSH suppression leads to spermiation failure initially, but ultimately disrupts earlier germ cell development, reviewed in (O'Donnell et al., 2011). In this setting, the early induction of spermiation failure in some men undergoing hormone-based contraception can lead to azoospermia (zero sperm in the ejaculate), despite the fact that their testes continue to produce spermatids. The degree of spermiation failure induced by hormone-based contraception can influence whether an individual achieves azoospermia or continues to produce sperm in the ejaculate (O'Donnell et al., 2001). Therefore the induction of spermiation failure can influence the efficacy of hormone-based contraception.

While spermiation is a determinant of sperm counts and fertility, it can also presumably influence sperm quality. Other than determining whether sperm are released or not, spermiation also accomplishes the removal of the spermatid cytoplasm to ensure its streamlined form that is necessary for normal motility. The failure to properly remove cytoplasm results in abnormal spermatids in the epididymis and usually infertility, as demonstrated in a number of transgenic mouse models, reviewed in (O'Donnell et al., 2011). However the contribution of spermiation failure to conditions of human male infertility is not well defined. It is known that excess cytoplasm on human spermatozoa (which likely arises from defective spermiation) is associated with increased generation of reactive oxygen species (ROS) which can induce DNA damage in the sperm and decrease its reproductive potential (Aitken and De Iuliis, 2010).

Conclusion

In conclusion, spermiation is a long, complex and multistep process, where the final goal is to release a streamlined spermatozoon. The process involves removal of the extensive cytoplasm from the mature elongated spermatid, and the removal of the ES junction that has enabled the Sertoli cell to tightly adhere to the spermatid during its elongation and development. The spermatid is pushed out into the lumen as its cytoplasm is “stripped” off by the Sertoli cell. As the ES junction is removed, another integrin-based focal adhesion-like junction maintains tight adhesion of the spermatid to the Sertoli cell. The remodeling of ES junctions during spermiation, and perhaps some aspects of cytoplasm removal, is mediated by TBCs which are specialized endocytic structures in Sertoli cells. The final release of sperm from the Sertoli cells is termed disengagement, and involves an instantaneous loss-of-adhesion event likely mediated by signaling pathways in the Sertoli cell. Because of its multi-faceted nature and the involvement of numerous adhesion and signaling molecules, spermiation is highly vulnerable to disruption by various environmental insults and the suppression of hormones. Spermiation is a key determinant of sperm content, and possibly sperm quality, in the ejaculate and thus the success of this process is important for male fertility.

Testis Cell Isolation and Culture

The testis, the male gonad in animals, produces male germ cells and sexual hormones. It contains several primary cell types. Germ cells, Sertoli cells and peritubular cells are located within the seminiferous tubules. Germ cells are developed in the tubules supported by the two types of somatic cells, Sertoli and peritubular cells. In between tubules (interstitium) Leydig cells are present. Leydig cells are the location of steroidogenesis and synthesize hormones essential for germ cell differentiation (Christensen and Mason, 1965) (Fig. 1).

The procedures for isolating individual testis cell populations for culture are very similar across the animal spectrum. In 1969, Hall et al. were able to look at interstitial versus tubular cell types by manually dissecting the testis. Welsh and Wiebe (Welsh and Wiebe, 1975) introduced in 1975 an isolation method using the enzyme collagenase, which worked well for digesting the tissue without hurting viability of the isolated cells, and Dornington et al. (1975) published a similar method in the same year that used the enzymes trypsin, desoxyribonuclease (DNase) and collagenase. Tung et al. (1984) improved the enzymatic digestion method by adding hyaluronidase which helped to reduce cross contamination of cell types. This method of using progressive steps of enzymatic digests has been used with slight modifications for isolation of individual testicular cell fractions from a wide range of species. The three enzymes trypsin, collagenase and hyaluronidase together with DNase are used for most protocols, but the order and combination in which they are used may change depending on the animal species and cell type to be isolated.

The following is a technique used for the isolation of testis cells from immature rats (around 20 days of age). In 20 d rats the Sertoli cells cease to divide and comprise a large fraction of the testicular cell types because spermatogenesis has not started yet and so the proportion of germ cell contamination in the Sertoli cell fraction is low (Fig. 2).

Sertoli Cell and Peritubular Cell Isolation and Purification (Tung et al., 1984 With Modifications)

The rats are sacrificed and testes removed from each rat. After rinsing the testes several times in sterile HBSS (Hank's Buffered Salt Solution) they are detunicated (the tunica albuginea encloses the testis) and minced finely. The initial enzymatic digest uses trypsin (protein hydrolysis) and DNase. The addition of DNase is necessary at every purification step for removal of the DNA released from damaged cells, otherwise the cells would clump together into a gelatinous mass and be impossible to separate. The trypsin digest will separate the tubules, and interstitial cells (Leydig cells etc.) will be freed and can be separated from the tubules by gravity sedimentation. The tubules will settle to the bottom of the tube and the supernatant can be discarded. Several washes of the tubules using gravity sedimentation are needed to guarantee that most of the interstitial cells are removed. The next step in the procedure involves collagenase (serine protease) digestion, again with DNase added. This step will break the tubules into smaller pieces and release a large percentage of the peritubular cells. The tubule pieces (with Sertoli cells attached) can be separated from the peritubular cells by gravity sedimentation. The tubules will settle to the bottom and peritubular cells can be removed with the supernatant. The peritubular cells can be washed to remove cellular debris and enzymatic solution by pelleting the supernatant gently in a centrifuge, and then resuspending the peritubular cells in a physiological buffer. After several washes, they can be plated in appropriate medium for further study in cell culture. The remaining tubules need to be washed again several times to remove as many contaminating peritubular cells as possible and will then be further digested with hyaluronidase and DNase. This step will

Fig. 1 Cell types in the testis. Modified from Skinner, M. K. (1991). Cell-cell interactions in the testis. *Endocrine Reviews* 12, 45–77.

Fig. 2 Flowchart for isolation of different cell types from the testis.

further break down the tubules, releasing the germ cells and remaining peritubular cells. In a microscopic check the Sertoli cells can be seen as small aggregates and after several washes using gravity sedimentation of the Sertoli cell aggregates, they can be plated in the appropriate medium. If further dissociation is needed before plating they can be homogenized by shearing using a hypodermic needle with small needle size and passaged through a cell strainer which will result in a single cell suspension. Also, if needed, a hypotonic shock (using a 1:10 dilution of Hank's Balanced Salt Solution—HBSS with water) can be added after preparation of Sertoli cells which will not damage the Sertoli cells but will burst and get rid of remaining germ cells (Galdieri et al., 1981). This is especially important in the preparation of Sertoli cells from adult testes since spermatogenesis is present at that time and contamination with germ cells could pose a problem in the cell culture. In addition germ cells will not attach to the culture plate like Sertoli cells and will die after a few days in culture. So, the purity of Sertoli cells will increase after a few days in culture.

Leydig Cell Isolation and Purification (Risbridger and de Kretser, 1986; Klinefelter et al., 1987 With Modifications)

The testis interstitium contains a mix of Leydig cells, macrophages, epithelial cells, and fibroblasts. As mentioned before, Leydig cells synthesize hormones important for sexual development and germ cell differentiation and are needed for study in that context. Testes are prepared as described above and digested with collagenase until the testes start to dissociate into tubules, thus releasing the interstitial cells. Over-digestion needs to be avoided in order to keep the tubules intact and avoid contamination of the Leydig fraction with tubular cells. The interstitial cells will be in the supernatant after letting the tubules settle out and are removed for further processing. Density gradients such as Percoll gradients are used to separate Leydig cells from other interstitial cells. The interstitial mix will be loaded on a Percoll gradient and spun at low g. The Leydig cells will concentrate at a certain Percoll density and can be isolated as a pure fraction. The Percoll needs to be washed off before plating the cells for cell culture.

Testicular Macrophage Isolation and Purification (Yee and Hutson, 1983)

Testicular macrophages are the main immune cells of the mammalian testis. There are two different populations which differ in morphology and localization (in the interstitium or on the surface of seminiferous tubules). They are involved in classical immune functions but also in organogenesis, spermatogenesis and male hormone production.

The protocol in the original paper describing isolation of testicular macrophages from mammalian testis (Yee and Hutson, 1983) is still being used with minor modifications. After decapsulating the testes and washing them in PBS, the testes are minced and then incubated with a digestive enzyme like trypsin or collagenase with DNase added. The seminiferous tubules are allowed to sediment and the supernatant is collected and centrifuged. The pellet containing a mixture of interstitial cells is resuspended in serum free medium or PBS and plated on plastic cell culture dishes. Under these conditions the macrophages will attach, but not the other cells. After only a short incubation period of about 20–30 min the non-adherent cells are washed off and the remaining—adherent—cells constitute the macrophage fraction which has a purity of over 95% (Winnall et al., 2011).

Germ Cell Isolation and Purification (Bellvé, 1979 With Modifications)

Germ cells at different stages of spermatogenesis can be isolated depending on the age of the animal used for preparation. But especially for mammals it is difficult to grow germ cells in culture by themselves, with the exception of spermatogonial stem cells. Sertoli cells are essential for the structural support and paracrine control (through for example testosterone and FSH) of germ cells during spermatogenesis. Therefore Sertoli cells are often used in a co-culture with germ cells to study the stages and regulation of spermatogenesis. Still, it is difficult to achieve complete spermatogenesis in cell culture, but it can be done in organ cultures using testis fragments as described below in section Testis Organ Culture.

Isolation of germ cell fractions follows essentially the same enzymatic digestion protocol as used for somatic testis cells. An initial enzymatic digest with trypsin or collagenase will release interstitial cells and the majority of peritubular cells, which will stay in the supernatant during gravity sedimentation and can be discarded while tubule fragments and Sertoli cell/germ cell clusters will be in the pellet. Further enzymatic digestion with trypsin/EDTA and DNase will fully dissociate the seminiferous tubules and release Sertoli and germ cells.

A germ cell fraction can be isolated different ways. Panning is an efficient method for crude separation of germ cells from Sertoli cells and relies on the fact that Sertoli cells will stick to a culture plate while germ cells will not. So, after plating and a 2–3-day incubation the germ cells can be removed from the top of the plate leaving the Sertoli cells behind. Germ cells can then be further purified based on their density using a gradient made with BSA (bovine serum albumin) or Percoll. Another approach is to remove Sertoli cell clusters with a cell strainer which will result in a single cell germ cell fraction in the filtrate. Again, this fraction can be further purified using a gradient.

Sometimes it is necessary to isolate germ cells at a specific developmental stage and this can be done using a Sta-put ([Romrell et al., 1976](#); [McCarrey et al., 1992](#)) apparatus, which is a velocity sedimentation cell separator allowing the isolation of cell fractions based on their differences in gravity sedimentation rate. Germ cells at different stages of development have different sedimentation rates.

Cell culture of germ cells can be accomplished by co-culturing them with feeder cells like Sertoli cells. This co-culture can be improved by growing the cells on specific substrates like Matrigel, collagen or in a soft-agar culture. Also, growth in 3-D culture systems providing “scaffolding” for the germ cells has shown promise in improving germ cell viability and growth ([Hunter et al., 2012](#); [Stukenborg et al., 2009](#)).

Testis Organ Culture (Dores et al., 2012)

Cell culture systems are very helpful because they reduce a complex structure into smaller parts and therefore help one to understand complicated processes by examining and manipulating the single parts of the system. An in vitro cell culture system is indispensable for studying cell–cell interactions, roles of hormones and growth factors, gene expression and morphological changes. Some processes however, for example spermatogenesis, need a more intact system to function properly in order to fully finish their developmental events. So far it has not been possible to produce functioning spermatozoa using an in vitro cell culture system alone.

Organ culture on the other hand preserves the proper niche of testicular structure and paracrine exposures which are needed for proper spermatogenesis. Organ culture of testis fragments can be maintained for several weeks. Testis organ culture’s main use has been to study spermatogenesis with clinical implications for help with reproductive issues.

Organ culture protocols often use the air–liquid interface method ([Trowell, 1954](#)) in which a filter is carefully set on top of the appropriate cell culture medium into a well of a multi-well cell culture plate ([Levine et al., 2000](#)). It is important that the filter float on top of the medium and is not submerged. A small piece of testicular tissue or a whole embryonic testis are placed on the filter floating on cell culture medium. The testis piece or embryonic whole testis will be covered with a drop of medium to prevent it from drying out. This places the organ culture close to the atmosphere in the incubator, and allows for higher oxygen concentrations in the cultured organs. Instead of just using liquid medium, other supporting substrates like agarose can also be used ([Stukenborg et al., 2008](#)). These more solid substrates can be saturated with medium with the testis piece placed on top. Incubation of the organ culture in a CO₂ cell culture incubator can continue from a few days to several weeks with frequent medium changes.

Human testicular pieces have been cultured this way for about 2 weeks with decreasing germ cell numbers throughout this time ([Roulet et al., 2006](#)). [Nakamura et al. \(2017\)](#) could maintain a mouse testis organ culture with spermatogenesis for over 2 months. One of the most important features to maintain a fully functioning organ culture seems to be the proper medium and additives. For example, a change in the medium from serum to serum replacements like GlutaMax® and AlbuMax® made a big difference in successfully maintaining organ cultures for longer periods of time and achieving full spermatogenesis. These experiments have been mostly done with mammalian tissue, but with appropriate culture conditions could probably be extended to other species.

Summary

Cell and organ culture of testis cells or testis tissue from a variety of species is advancing the understanding of processes in the testis on both a molecular and whole system level. Cell and organ culture together provide means in basic and applied research to investigate this complex organ in detail providing information on organogenesis, male germ cell production, the specific cell types and their ways of interacting, and the signaling pathways controlling testis function.

This knowledge is invaluable for finding out more about the mechanisms of spermatogenesis, which provides the means to develop new diagnostic tools and therapies for restoring male fertility and for assisted reproduction. It will also be helpful, for example, for preservation of gametes, maintenance of livestock and species conservation. Organ cultures in particular are needed for research where the intact testis structure is required, as in toxicological studies and for in vitro maturation of sperm cells.

Blood-Testis Barrier

Baiping Mao, Ming Yan, Linxi Li, and C Yan Cheng, Population Council, New York, NY, United States

Introduction

The blood-testis barrier (BTB), also known as the Sertoli cell epithelial barrier, is one of the tightest blood-tissue barriers in the mammalian body (Setchell, 2008; Franca et al., 2012; Cheng, 2012; Cheng and Mruk, 2012; Pelletier, 2011; Stanton, 2016; Mital et al., 2011). In 1964, the term BTB was first coined by Chiquoine in a report, examining the morphological events during cadmium-induced testis injury (Chiquoine, 1964), which is known to cause male sterility when administered at acute doses in rodents (Parizek and Zahor, 1956; Parizek, 1960). However, the concept of the BTB was first reported more than 100 years ago when dyes administered to rodents, which stained virtually all organs except the brain and seminiferous epithelium of the testis (Setchell, 2008; Setchell and Waites, 1975), illustrating there is a unique blood-tissue barrier in the testis and the brain to protect these two vital organs in mammals, and subsequently called the blood-testis barrier and the blood-brain barrier, respectively. These findings also illustrate that microvessels in the interstitial space, located at the intersections of seminiferous tubules in the interstitium, contribute virtually no barrier function to confer the BTB function in the testis. Interestingly, in rodents, peritubular myoid cells form a single cell layer behind the basement membrane and type I collagen layer versus several layers of myoid cells in primates around the seminiferous tubule (Setchell and Breed, 2006). This peritubular myoid cell layer in rodents has been shown to be an effective barrier in blocking the passage of electron dense markers such as colloidal carbon or lanthanum across the tunica propria since ~85% of tubules were capable of blocking electron dense substances from entering the seminiferous epithelium (Fawcett et al., 1970; Dym and Fawcett, 1970). These findings thus illustrate that peritubular myoid cell layer is a considerably important contributor to the BTB function in rodents. This conclusion was reached because the myoid cell layers in primates that wrap around the seminiferous tubules are not effective in blocking the passage of electron dense markers across seminiferous epithelium when administered via i.v. (Dym, 1973). In short, the BTB in primates and possibly humans is solely dependent on the Sertoli cells for the provision of the needed barrier function to support spermatogenesis. As such, the BTB is also known as the Sertoli cell epithelial barrier in the testis.

In the mammalian testis, the BTB is located near the basement membrane, which also segregates the seminiferous epithelium into the basal and the adluminal (apical) compartment (Fig. 1). Due to the presence of the BTB, Sertoli cells and germ cells at different stages of their development are the only cell types found in the seminiferous epithelium, whereas Leydig cells, residual macrophages, and microvessels are found in the interstitium. Spermatogonial stem cells (SSC), also referred to as (or including) A_{single} (A_s) in rodents vs. A_{dark} in humans reside in the stem cell niche (de Rooij, 2009; Ehmcke et al., 2006); undifferentiated spermatogonia including A_{paired} (A_{pr}) and A_{aligned} (A_{al}) vs. A_{pale} in humans; and differentiated spermatogonia including $A1-4$, $A_{\text{intermediate}}$ (A_{in}) and type B spermatogonia in rodents vs. B spermatogonia in humans (Cheng and Mruk, 2012; Ehmcke and Schlatt, 2006) are all residing in the basal compartment. Once type B spermatogonia transform to preleptotene spermatocytes in the basal compartment in both rodents and humans, these are the only germ cells that are being transported across the BTB, at stage VIII of the epithelial cycle in rodents vs. stage III in humans (Hess and de Franca, 2008; Parvinen, 1982; Amann, 2008; Chen et al., 2017a) while differentiating into leptotene spermatocytes. As such, zygotene and pachytene transform to diplotene spermatocytes, preparing for meiosis I/II in stage XIV vs. XII tubules in the rat and mouse testis (and stage VI tubules in humans), respectively, to form haploid spermatids (step 1). Step 1 spermatids in turn undergo extensive differentiation and transformation including 19 or 16 steps in rat or mouse testes (and 6 steps in humans), respectively, to become elongated spermatids via spermiogenesis. As such, fully developed spermatids (i.e., spermatozoa) line-up at the adluminal edge against the tubule lumen to prepare for their eventual release at spermiation at stage VIII of the epithelial cycle in both rat and mouse testes (and stage II in humans). Thus, for spermatids, all the cellular events pertinent to the post-meiotic development take place strictly in the adluminal compartment, behind the blood-testis barrier, suggesting that BTB may be crucial to support meiosis and post-meiotic spermiogenesis. In fact, studies in rodents have shown that the assembly of a functional BTB is crucial for the completion of meiosis I/II. For instance, treatment of neonatal rats with diethylstilbestrol (DES, a synthetic nonsteroidal estrogen) that delayed the establishment of a functional BTB by 4-weeks also delayed the first wave of spermiogenesis, such as meiosis I/II by 4-weeks, since pachytene spermatocytes failed to enter meiosis but underwent degeneration (Toyama et al., 2001), leading to meiotic arrest. On the other hand, exposure of rodents to acute doses of toxicants, such as cadmium or glycerol known to induce irreversible BTB damage, also induced infertility in which spermatocytes failed to enter meiosis (Hew et al., 1993; Wiebe et al., 2000; Setchell and Waites, 1970; Siu et al., 2009). Collectively, these findings illustrate the significance of the BTB to support spermatogenesis.

It is of interest to note that the testis is an immune-privileged organ (Kaur et al., 2013, 2014). Immune privilege is a concept referring to a specific site in the mammalian body, such as the testis, the brain, and the eye which are known immune privilege sites since they can protect grafted tissue (e.g., when skin is transplanted to one of these organs) from rejection by the host animals (Medawar, 1948; Brent, 2016). There are two different aspects of immune privilege, namely privileged sites and privileged tissues. A privileged site refers to a site in which foreign tissue grafted to that site can survive longer, or even indefinitely, than in a nonprivileged site. A privileged tissue is a tissue that resists rejection when grafted into a nonprivileged site. The testis is a unique organ because it is having both aspects of the immune privilege (Fijak and Meinhardt, 2006). Studies have shown that Sertoli cells in the testis are responsible to confer the testis as an immune privileged organ (Kaur et al., 2014), possibly through its secretory

Fig. 1 A schematic drawing illustrates the relative location and morphological features of the blood-testis barrier (BTB) in relation to other cell junctions in the seminiferous epithelium of adult rat testes. The top panel is the cross-section of a typical adult rat testis, showing an early stage VIII seminiferous tubule, illustrating different germ cell types across the seminiferous tubule. The relative location of the BTB that segregates the seminiferous epithelium into the basal and the adluminal compartments is also noted. The bottom panel is a schematic drawing of the seminiferous epithelium. The BTB is constituted by both actin-based tight junction (TJ), basal ectoplasmic specialization (basal ES), and gap junction (GJ), as well as the intermediate filament-based desmosome. It also segregates the epithelium into the basal and the adluminal compartments. The most notable morphological feature of the BTB is the two arrays of actin filament bundles that are sandwiched in-between the apposing Sertoli cell plasma membranes and the cisternae of endoplasmic reticulum. At the interface of all other germ cell types (except step 8–19 spermatids) and Sertoli cells, they are supported by GJ and desmosome. However, there is only one anchoring junction type found between Sertoli cells and step 8–19 spermatids, namely the apical ES. The apical ES is morphologically similar to the basal ES except that only one array of actin filament bundles is noted since no unique morphological feature is contributed by the elongating/elongated spermatids when examined by electron microscopy. Scale bar, 60 μm.

biomolecules including both cytokines (e.g., interleukins, interferons) and immunosuppressive biomolecules whose identities remain to be elucidated. In fact, recent studies have shown that Sertoli cells are unique components of successful xenografts in treating different diseases such as diabetes that is prone to tissue rejection when pancreatic islet cells from one species are grafted to another species (Luca et al., 2015, 2016; Bistoni et al., 2012).

Herein, we summarize findings regarding the biology of the BTB on topics that have not recently been reviewed. Thus, many of the background information on BTB is not covered in details herein since these topics have been discussed in several recent reviews (Franca et al., 2012; Pelletier, 2011; Stanton, 2016; Kaur et al., 2014; Mruk and Cheng, 2015; Li et al., 2016). Readers are encouraged to seek the needed information from these reviews.

Blood-Testis Barrier (BTB)—Structural and Morphological Features

As noted above, the BTB is not conferred by endothelial cells of the microvessels in the interstitium, except that in rodents (but not primates), the peritubular myoid cell layer in the tunica propria located behind the basement membrane and the type I collagen layer contribute some of the barrier function. Instead, the BTB is created by adjacent Sertoli cell junctions near the base of the seminiferous epithelium as noted in Fig. 1. The major actin-based cell-cell anchoring junction type that is responsible for the BTB integrity, similar to other blood-tissue barriers, is the tight junction (TJ) between adjacent Sertoli cells which create a belt-like structure near the base of the seminiferous epithelium (Fig. 2). However, unlike TJs found in other blood-tissue barriers, the TJ at the Sertoli cell BTB coexists with another testis-specific actin-based adherens junction (AJ) called the basal ectoplasmic specialization (basal ES), as well as the gap junction (GJ), which collectively contribute to the belt-like structure that encircle the base of the seminiferous epithelium (Fig. 2). These junctions, namely TJ, basal ES and GJ together with the intermediate filament-based desmosome constitute the BTB (Fig. 2). As noted in Fig. 1, the basal ES is the most notable junction at the BTB that confers the unusual adhesive strength of the immunological barrier. The basal ES is typified by the presence of two arrays of actin filament bundles, one each on the cytoplasm of the two adjacent Sertoli cells that are sandwiched in-between the apposing Sertoli cell–cell plasma membranes and cisternae of the endoplasmic reticulum (Fig. 1). Interestingly, basal ES coexists with TJ, thereby the unique actin filament bundles confer strong adhesive function to the BTB, whereas the GJ provides the needed intercellular communications to fine-

Fig. 2 Morphological features of the Sertoli cell BTB in vitro and in vivo. Sertoli cells are known to establish a functional TJ-permeability barrier when cultured in vitro which mimics the Sertoli cell BTB in vivo. In (A), Sertoli cells cultured in vitro for ~2–3 days established a functional TJ-barrier, which is supported by the F-actin (green fluorescence) and microtubules (MT; shown herein is the α -tubulin, green fluorescence, with together with the β -tubulin are the building blocks of MTs) that stretched across the Sertoli cell cytosol. These cytoskeletons thus support the establishment of the Sertoli cell TJ-barrier as noted by the precise localization of TJ adaptor protein ZO-1 (zonula occludens 1) and basal ES integral membrane protein N-cadherin at the Sertoli cell cortical zone, as these adhesion proteins utilize actin for attachment. Scale bar, 40 μ m, which applies to other micrographs in this panel. In (B), this is the typical result of an in vivo BTB integrity assay wherein functional BTB is located near the base of the each seminiferous tubule that blocks the diffusion of a membrane impermeable biotin (such as sulfo-NHS-LC-biotin from Thermo Fisher Scientific, green fluorescence when biotin is visualized with Alexa Fluor 488-streptavidin as described (Gao et al., 2016)) across the immunological barrier to enter the adluminal compartment. In short, biotin (green fluorescence) is restricted to the interstitial space and the basal compartment. Scale bar, 300 μ m.

tune various junction types at the BTB to maintain its homeostasis to support the barrier function throughout the epithelial cycle of spermatogenesis (Li et al., 2012, 2010). Altogether, these junctions create a unique blood-tissue barrier in the testis in which the BTB is capable of blocking the diffusion of even a small membrane impermeable molecular probe, sulfo-NHS-LC-biotin (Mr 556.59), from crossing the barrier to enter the adluminal compartment as noted in Fig. 2, which illustrates the tightness of this immunological barrier based on a typical in vivo BTB integrity assay.

Functions of the BTB

The BTB has multiple functions in the testis to support spermatogenesis. First, the BTB creates a unique microenvironment in the adluminal compartment of the testis to support meiosis and spermiogenesis by segregating serum proteins, electrolytes, mineral salts, water, and virtually all other somatic cells including immune cells from entering the space behind the barrier (Figs. 1–2). Second, the BTB also determines the fluid composition and microenvironment of the seminiferous tubule since studies have shown that the levels of proteins, electrolytes, hormones (e.g., testosterone), mineral salts, cytokines and other biomolecules found in the seminiferous tubule fluid or in the rete testis compartment are considerably lower from the testicular lymph and serum (Setchell and Waites, 1975; Turner et al., 1984; Setchell et al., 1978; Setchell, 1980). This function of the BTB is achieved through its role in regulating the paracellular (between adjacent Sertoli cells) and transcellular (through intracellular transport pathway, such as receptor or endocytic vesicle-mediated transport) transport of substances across the barrier. Due to the presence of the actin microfilament bundles of the basal ES which coexists with the TJ, virtually no substances including water, electrolytes, nutrients (e.g., glucose), hormones and biomolecules can penetrate the BTB unless specific receptors are present on the surface of Sertoli cells (e.g., FSH receptors) (Setchell, 2008; Bardin et al., 1988; Griswold, 1998). However, the BTB is not entirely impenetrable since it allows the passage of certain (including proteins and biomolecules) but not all molecules (e.g., proteins), illustrating its selectivity function (Cheng and Mruk, 2012; Tung et al., 2017). For instance, a recent report has shown that some meiotic germ cell antigens (MGCA) expressed on sperm are being sequestered behind the BTB, however, some non-sequestered MCGA are transported outside the BTB as cargoes and discarded (Tung et al., 2017). However, the mechanism(s) that regulate this type of selectivity remains unknown. For instance, the biomolecule(s) and the molecular mechanism(s) that trigger and determine this selectivity remain to be elucidated.

Regulation of the BTB—An Emerging Concept of Regulation

The topic on the regulation of BTB function is the subject of several recent reviews which include the involvement of mTOR (mammalian target of rapamycin) (Li and Cheng, 2016; Mok et al., 2013), FAK (focal adhesion kinase) (Li et al., 2013; Cheng and Mruk, 2009; Wan et al., 2014), Src family kinases (e.g., c-Src, c-Yes) (Li et al., 2016; Xiao et al., 2012; Chojnacka and Mruk, 2015), ICAMs (intercellular adhesion molecules, including ICAM-1 and ICAM-2) (Xiao et al., 2013; Mruk, 2016), cytokines (Lie et al., 2012; Lui and Cheng, 2007; Xia et al., 2005), MAPKs (Li et al., 2009) and cytoskeletons (Tang et al., 2016; Lie et al., 2010, 2011). Thus, these topics are not covered herein to avoid redundancy. Instead, we summarize findings based on a series of recent reports, depicting an emerging concept regarding the presence of an autocrine-based local regulatory axis that modulates BTB function.

F5-Peptide—A Peptide Derived From Laminin- γ 3 Chains at the Apical ES That Regulates BTB Dynamics

During stage VIII of the epithelial cycle, fully developed spermatids transformed to spermatozoa begin to line-up in the adluminal compartment against the tubule lumen to prepare for their release at spermiation in late stage VIII tubules. Laminin- γ 3 chain, one of the constituent proteins of the apical ES that forms a bona fide adhesion protein complex (Yan and Cheng, 2006) with α 6 β 1-integrin (Palombi et al., 1992; Salanova et al., 1995), is cleaved at its domain IV, likely through the action of MMP2 (metalloprotease 2) which was shown to be highly expressed in stage VIII tubules (Siu and Cheng, 2004a), to release a biologically active peptide called F5-peptide (Yan et al., 2008; Su et al., 2012). Studies have shown that this 50-amino acid peptide is capable of inducing remodeling of the Sertoli cell BTB both in vitro (Yan et al., 2008) and in vivo (Su et al., 2012; Gao et al., 2016). More important, the disruptive effects of the F5-peptide on BTB integrity is highly reversible (Su et al., 2012; Gao et al., 2016), possibly because this BTB regulator is produced endogenously to support spermatogenesis. Furthermore, F5-peptide is also able to potentiate further breakdown of apical ES, thereby facilitating spermiation (Gao et al., 2016). In short, these findings also illustrate its potential of serving as a naturally occurring reversible male contraceptive peptide if it can be delivered to the testis at an appropriate dose. Studies have shown that laminin- γ 3 chain is not an integrated membrane protein since it is lacking a transmembrane domain (Yan and Cheng, 2006; Koch et al., 1999). Thus, it likely adheres onto the spermatid cell surface to form a bona fide adhesion complex with the Sertoli cell specifically expressed α 6 β 1-integrin (Palombi et al., 1992; Salanova et al., 1995). When domain IV of the laminin- γ 3 chain is cleaved by MMP2, the F5-peptide either needs to be transported inside the Sertoli cell if it is internalized to exert its biological action via an “inside-out” signaling cascade or it exerts its effects through an “outside-in” signaling cascade (Durrant et al., 2017; Patsoukis et al., 2017). Indeed, F5-peptide was found to utilize the peptide

transporter 1 (also known as solute carrier family 15 member 1, SLC15A1) expressed in Sertoli cells to enter Sertoli cells to exert its effects (Su et al., 2015). On the other hand, signaling studies have shown that F5-peptide exerts its biological effects through either “inside-out” or “outside-in” signaling (Su et al., 2012), illustrating the testis is equipped with a highly sophisticated signaling network to regulate BTB dynamics. Presently, the receptor that works in concert with F5-peptide in the testis remains unknown, however, studies have shown that laminins and/or fragments of laminin chains usually serve as the ligand to activate integrin-based signaling pathway (Pozzi et al., 2017; Combes et al., 2015; Yan et al., 2007). It is likely that an integrin-based receptor expressed at the basal ES/BTB to serve as the putative receptor for the F5-peptide. Recent studies have shown that F5-peptide exerts its disruptive effects through changes in actin- or microtubule (MT)-binding and regulatory proteins, which in turn perturbs the organization of actin- and MT-based cytoskeletons (Gao et al., 2016). For instance, following overexpression of F5-peptide in the testis in vivo using a mammalian expression vector pCI-neo vs. empty vector alone (to serve as a control) for transfection with a transfection efficiency of ~60%, F-actin organization across the entire seminiferous epithelium in the treatment group was considerably disrupted (Su et al., 2012; Gao et al., 2016). These disruptive changes include: (i) the prominent track-like structures surrounding elongating spermatids that are being transported across the epithelium in stage V tubules were grossly disrupted, appearing as truncated actin filaments; (ii) F-actin no longer localized robustly at the apical ES, appearing as bulb-like structures at the concave side of spermatid heads found in control testes, instead, F-actin was diffusely localized; (iii) the F-actin at the basal ES/BTB was no longer tightly localized at the site to support BTB function, thereby perturbing the BTB integrity as noted in an in vivo BTB integrity assay (Gao et al., 2016). More important these changes were the result of disruptive spatiotemporal expression of the actin barbed end capping and bundling protein Eps8 and also the branched actin polymerization-inducing protein Arp3. As such, the F-actin network at the ES favored the configuration of a branched/unbundled organization (Gao et al., 2016), no longer supporting apical and basal ES function. Furthermore, the MT-conferred tracks that were robustly expressed across the seminiferous epithelium and were aligned almost perpendicular to the basement membrane noted in control testes were also found to be grossly disrupted following overexpression of F5-peptide in the testis (Gao et al., 2016). They were either truncated and/or mis-aligned, by laying parallel to the basement membrane, thereby failing to support the transport of spermatids and also organelles (e.g., endosomes, phagosomes, residual bodies) across the epithelium. As such, groups of elongated spermatids were trapped deep inside the epithelium in late stage VIII, IX, and even X or XI tubules (Gao et al., 2016). The significance of these findings is that there is a local autocrine-based functional axis that links the apical ES and the basal ES/BTB across the seminiferous epithelium, known as the apical ES-basal ES/BTB axis. In short, F5-peptide released at the apical ES site at spermiation during stage VIII of the epithelial cycle can potentiate apical ES degeneration but also induces basal ES/BTB remodeling to support the transport of preleptotene spermatocytes across the immunological barrier. As such, the two cellular events that take place at the opposite end of the seminiferous epithelium, namely spermiation and BTB remodeling, are coordinated in stage VIII tubules.

NC1 (Non-Collagenous 1) Domain Peptide—A Peptide Derived From the Basement Membrane Collagen α 3(IV) Chain That Regulates BTB Dynamics

Earlier studies have shown that using antibodies prepared against the collagen chains found in the basement membrane were capable of perturbing the Sertoli cell TJ-permeability barrier function (Siu et al., 2003), illustrating there is a potential functional axis between the basement membrane and the BTB to modulate BTB function to support spermatogenesis. Subsequent studies have shown that the C-terminal noncollagenous (NC1) domain of ~230 amino acid residues derived from collagen α 3 (IV) chain (i.e., type IV collagen α 3 chain, a major constituent component of the basement membrane) when cleaved by the action of MMP9 in the basement membrane (Siu and Cheng, 2004b), is capable of inducing Sertoli cell TJ-permeability barrier function (Wong and Cheng, 2013). Similar observations are obtained either by using purified recombinant NC1 domain protein (Wong and Cheng, 2013) or through the use of a cDNA clone encoding NC1 domain for its overexpression using the pCI-neo mammalian expression vector (Chen et al., 2017b). It was also noted that the NC1 domain generated at the basement membrane was transported across the seminiferous epithelium to reach the apical ES site using an MT-dependent transport mechanism (Chen et al., 2017b). This conclusion is reached based on the finding that the use of Taxol (a drug that specifically stabilizes MTs by preventing MT depolymerization, thereby disrupting MT dynamics) was found to block the transport of NC1 domain across the seminiferous epithelium by perturbing MT organization, and Taxol had no apparent effect on F-actin organization in the epithelium (Chen et al., 2017b). More important, NC1 domain is capable of inducing BTB integrity in the testis in vivo through disruptive changes in the organization of F-actin and also MTs across the epithelium (Chen et al., 2017b). Besides its effects at the BTB, NC1 domain was also found to induce apical ES degeneration by perturbing the spatiotemporal expression of actin regulatory proteins such as Arp3 and Eps8, thereby perturbing F-actin organization (Chen et al., 2017b). Since adhesion protein complexes, such as laminin-integrin and nectin-afadin, are actin-based apical ES proteins, a disruption of F-actin thus perturbs their localization, causing apical ES degeneration that leads to spermatid exfoliation from the epithelium, mimicking spermiation. Taking these data collectively, NC1 domain is another autocrine-based peptide generated at the basement membrane during the epithelial cycle to modulate BTB remodeling to support spermatogenesis. These findings also confirm the notion that there is a local apical ES-BTB-basement membrane functional axis in the testis to support spermatogenesis through its effects on the BTB. In this context, it is of interest to note that both F5-peptide and NC1 domain peptide exert their effects similarly by promoting BTB remodeling, causing the Sertoli cell TJ-barrier disruption.

Fig. 3 A schematic drawing illustrates the regulatory biomolecules in the apical ES-BTB/basal ES-basement membrane functional axis in the adult testis that modulate the integrity of the basal ES/BTB and apical ES. As detailed in text, biologically active F5-peptide released from the laminin-γ3 chain at the apical ES (at spermiation, via the action of MMP2) and also NC1 domain peptide from the collagen α3(IV) chain in the basement membrane (via the action of MMP9) have been shown to be crucial regulators of ES function. First, these peptides induce further breakdown of the apical ES to facilitate the release of sperm at spermiation. Second, these peptides are also capable of inducing basal ES/BTB remodeling to facilitate the transport of preleptotene spermatocytes across the immunological barrier. Since these events take place concurrently across the seminiferous epithelium at stage VIII of the epithelial cycle, they thus serve as important regulators to coordinate these cellular events during spermatogenesis. Furthermore, an 80 kDa biologically active generated at the basement membrane (via the action of MMP9) also modulates the basal ES/BTB function (and possibly the apical ES function) by promoting the integrity of the ES. In short, the action of the F5-peptide or NC1 domain is in sharp contrast to the 80 kDa fragment, making these biomolecules as molecular switches to promote ES restructuring and integrity (or stability), respectively.

80 kDa Fragment—A Peptide Derived From the Basement Membrane Laminin $\alpha 2$ Chain That Regulates BTB Dynamics by Promoting BTB Integrity

Since both F5-peptide and NC1 domain peptide are endogenously generated biologically active peptides to induce BTB remodeling which are also capable of potentiating apical ES degeneration to support spermiation, we seek to investigate if there is another functional loop that supports BTB function and also apical ES integrity instead of causing their disruption. As anticipated, it was shown that laminin- $\alpha 2$ chain, also a constituent component of the basement membrane, likely to be its 80 kDa fragment residing at its C-terminal region, was involved in maintaining BTB integrity (Gao et al., 2017a, b) (Fig. 3). This conclusion is reached based on the findings that a knockdown of laminin- $\alpha 2$ chain by RNAi using shRNA was capable of inducing Sertoli cell TJ-permeability barrier disruption (Gao et al., 2017b), illustrating its physiological function under normal conditions was to maintain BTB integrity. This 80 kDa fragment of laminin- $\alpha 2$ chain derived from the basement membrane appears to be transported to the apical ES site via a MT-dependent mechanism (Gao et al., 2017b). More important, the disruptive effects of the laminin- $\alpha 2$ shRNA on the BTB function were shown to be mediated through the mTORC1-p-rpS6 signaling pathway involving p-Akt1/2 by up-regulating p-rpS6 expression with a concomitant down-regulation of p-Akt1/2 expression (Gao et al., 2017a) (Fig. 3). Earlier studies have shown that the mTORC1-p-rpS6-Akt1/2 signaling pathway modulates BTB dynamics by disrupting BTB integrity (Mok et al., 2012, 2014) through disruptive changes in the organization of F-actin in Sertoli cells, which is mediated by a surge and a reduction in p-rpS6 and p-Akt1/2 expression, respectively (Mok et al., 2012, 2015). Collectively, these findings illustrate the presence of another feedback loop at the basement membrane-BTB axis in which collagen- $\alpha 2$ -derived 80 kDa fragment modulates BTB dynamics by making the Sertoli cell barrier “tighter” vs. the disruptive effects of the F5-peptide and the NC1-domain peptide which make the Sertoli cell barrier “leaky”. Thus, the combined effects of this 80 kDa laminin- $\alpha 2$ chain fragment vs. the F5-peptide and the NC1 domain peptide provide an efficient system to support BTB dynamics, such as to facilitate the transport of preleptotene spermatocytes across the immunological barrier at stage VIII of the epithelial cycle as depicted in the hypothetical model shown in Fig. 3.

Concluding Remarks and Future Perspectives

As briefly reviewed herein, it is likely that through these contrasting effects of different autocrine-based peptides at the apical ES-BTB/basal ES-basement membrane axis, the homeostasis of the apical ES and the basal ES/BTB can be precisely regulated at different stages of the epithelial cycle to support spermatogenesis, even though these ultrastructures are located at the opposite ends of the seminiferous epithelium. Since the two ultrastructures are linked underneath by both the F-actin and MT networks, their disassembly and reassembly can be easily coordinated through changes in the corresponding F-actin (e.g., Arp3, formin 1, Eps8, palladin) and MT (e.g., EB1, MARK4) binding and regulatory proteins. Fig. 3 thus summarizes results of these findings, depicting the role of the F5-peptide derived from laminin- $\gamma 3$ chain at the apical ES, and NC1 domain peptide derived from collagen $\alpha 3$ (IV) chain and 80 kDa fragment derived from laminin- $\alpha 2$ chain at the basement membrane on apical ES and basal ES/BTB integrity and function. However, some crucial questions have yet to be addressed. First, what is the upstream signaling molecule(s) that determines the activation of which functional axis, namely apical ES-basal ES/BTB, basal ES/BTB-basement membrane vs. apical ES/basement membrane axis, should be activated? Is that a cytokine or a defined stage of germ cells? How are these functional axis link to the known regulators of BTB dynamics, such as FAK, mTORC1, mTORC2, and SFKs (Src family kinases). Nonetheless, the hypothetical model shown in Fig. 3 provides many of the information necessary to design functional experiments in future studies.

Castration

Christine Aurich, Vetmeduni Vienna, Vienna, Austria

Methods for Castration

Castration includes any action by which an individual loses the use of his testes. This can be achieved either by surgical removal of the testes or by in situ destruction of testicular function. Methods comprise surgical, chemical, immunological, and endocrine approaches. Castration usually causes final loss of testicular functions with regard to both, the production of spermatozoa and testicular hormones. However, depending on the aim of castration, occasionally only one or the other effect may be desired. Sometimes, reversible castration might be required because of possible future reproduction of the respective male. In addition to surgical removal of the testes and epididymis, a variety of approaches for castration have been developed with the aim to offer cheaper, safer, or more diverse opportunities of controlling testicular function. Surgical castration is usually bilateral orchiectomy, that is, removal of both testes and epididymis, but may also include other surgical measures that result in loss of testicular function. Alternatively, chemical, hormonal, or immunological approaches for modulation of testicular function can be considered (Table 1). Chemical castration comprises the local, intratesticular use of pharmaceutical drugs and substances that cause coagulation and subsequent degeneration of testicular tissue. Exogenous substitution of hormones may result in interruption of the hypothalamus–pituitary–gonadal axis resulting in loss of testicular function. Immunological castration aims at the systemic production of specific antibodies reducing the release or action of hormones involved in the regulation of testicular function like GnRH or LH.

Reasons for Castration

The primary objective of castration is the control of reproduction. On a population basis, this aims at avoiding general overpopulation and limiting the transmission and spread of diseases (e.g., in free roaming dogs, cats, horses, or in wildlife populations). Castration on an individual basis is done to prevent for examples males with low genetic potential, carriers of congenital diseases (usually nonlicensed bulls or stallions) or bull calves in commercial beef systems from unwanted mating. It is also used in animals belonging to owners that do not want to produce any offspring for example, in pets or performance horses. Besides, many other reasons for castration apply and may differ considerably among species. Sexual behavior in male individuals—irrespective of species—often includes some degree of aggression or is related to unmanageable sexual drive or activity. Sexual behavior depends at least to a certain degree on testosterone production. Castration may therefore aim at modifying behavior and reducing behavioral problems. It will usually improve the manageability of males by humans. The handling of males especially in large domestic animal species like cattle, pigs, or horses can represent a serious safety concern. Male sexual behavior also often complicates animal husbandry by for example destruction of fences or enclosures when attempting to approach nearby oestrous females. Interestingly, also in humans, castration has been used as a—voluntary—measure for sex offenders, but the effectiveness and ethics of such treatments has been heavily discussed. Recently a similar discussion on castration of animals has started. Without medical reasons, castration of male animals is increasingly perceived as ethically questionable. In consequence, in some Scandinavian countries, gonadectomy of companion animals without medical reasons is no longer allowed. While in horses and mules, castration of nonlicensed stallions was for centuries routine because of an improved manageability of the castrated males, the percentage of stallions among riding and performance horses has recently considerably risen because an increasing amount of owners prefers intact male horses nowadays.

Table 1 Reasons for castration of males

|--|

In meat producing animals, castration affects carcass quality and prevents undesired sex-related taste and odor of heated meat in boars (also called boar taint) and male small ruminants. Boar taint is caused by skatole, a product of tryptophane breakdown in the gut, and by 16-androstene steroids (mainly androstenone) from the testis. It occurs in some, but not all postpubertal boars. In male small ruminants, a “sweaty” meat flavor has been attributed to the production of volatile acids but it has been proposed that accumulation of androstenone in adipose tissue could also contribute to the unpleasant odor of ram mutton. Nevertheless, the prevalence of castration in meat-producing animals varies with location: Castration as a measure to prevent boar taint involves 90% of male piglets in most European countries; however, in countries like the United Kingdom, Ireland, Spain, Portugal, and Australia, castration of male piglets is only rarely performed. Instead, male pigs are slaughtered at an earlier age, that is, before starting to present the boar taint (Rault *et al.*, 2011).

Castration is also a medical treatment for different reproductive pathologies in males. Benign hyperplasia of the prostate gland frequently occurs in aging men and dogs. The disease is androgen-dependent with overproduction of dihydrotestosterone within the prostate being the primary mediator. In dogs not used for breeding, castration is the most effective treatment. In men, application of a synthetic steroid type II 5 α reductase inhibitor is a successful treatment and also efficient in dogs for which castration is no option. Another disease with similarities between men and male dogs is prostate cancer which in men is usually treated by radical surgery and/or radiation therapy. Androgen deprivation is used with locally advanced or metastatic disease. The tumor is initially hormone-response, but in most cases develops into an androgen-independent neoplasm. Such a pathogenesis has also been suggested for the development of canine prostate carcinoma. However, many subtypes of prostate carcinoma with the exception of prostate adenocarcinoma are also found in castrated dogs. There is evidence that castration in dogs does not initiate the development of prostatic carcinoma, but supports tumor progression (Teske *et al.*, 2002). Therefore, castration is neither a preventative nor an effective treatment for the condition. Testicular neoplasia may occur in men and many domestic animal species, but in animals is mainly diagnosed in stallions and dogs. It will usually result in surgical removal of the affected testis. Equine arteritis virus causes abortion in mares and thus infection may result in considerable financial loss. Stallions persistently shedding the virus via semen form the main reservoir for the disease. After acute infection, the virus may persist in the accessory sexual glands of intact male horses for weeks or even years. Transient reduction of testicular androgen production by immunocastration will often terminate persistence of equine arteritis virus and is the treatment of choice for the condition in breeding stallions where surgical castration is no option.

Welfare Aspects

Castration of livestock but also of horses and companion animals is often done in the field with minimum financial expenditure although the procedure may have severe impact on animal welfare. It causes not only acute pain but also chronic discomfort during the postoperative period. This may also impair the animals’ performance with regard to feed intake and body weight gain. Pain and discomfort are related to traumatic injury, subsequent inflammation or tissue degeneration and necrosis. The degree of pain and discomfort may differ considerably with regard to species and age, castration methods as well as peri- and postoperative care. Responses to castration are considerably reduced by application of local anesthetics or nonsteroidal anti-inflammatory drugs at surgery (Webster *et al.*, 2013; White *et al.*, 1995). While such treatment is not an issue for humans, companion animals or valuable horses, castration of young livestock is traditionally performed without anesthesia or postoperative analgesia. Even today, there are only few European countries where the use of a local or general anesthetic for castration is mandatory (e.g., in Norway, Switzerland, and the Netherlands). However, pain management in association with castration is under discussion in many countries. The situation is often complicated by the fact that analgesic drugs may not be approved for pain relief in food producing animals in some countries. The pig industry argues against castration with anesthesia because of an increase in costs and workload, but also doubts the efficiency of such a treatment (Tuytens *et al.*, 2012). On the other hand, if managed properly the positive impact of castration of males on animal welfare should not be underestimated. Adult stallions and bulls will often be housed in single stalls without any social contact to conspecifics to avoid fighting, injury, or unwanted mating. In valuable breeding sires, this situation has to be accepted to a certain degree when refinement of their environment and proper care help to improve it. Similarly, in companion animals, uncastrated males are sometimes difficult to keep because their sexual drive and inappropriate behavior may annoy the owner. Indoor confinement or segregation from oestrous females is not always possible. Castration may also reduce the potential to show aggressive behavior in dogs. Castration will therefore help to provide these animals with a more pleasant life and reduce the risk that they end up in animal shelters. In animals that have already been sheltered, gonadectomy often improves adoptability, ensures that the animals will not repopulate shelters with their offspring, and increases the chance for retention in their adoptive homes (Root Kustritz, 2014). There is evidence that castrated dogs and cats in general have a longer lifespan than their intact conspecifics. Finally, it has to be taken into consideration that castration may affect not only the phenotype of a male but also general health of an individual because besides reproductive function, gonadal steroid hormones are involved in the regulation of several body systems. In humans, androgen deprivation therapy is effective in relieving symptoms of metastatic prostate cancer and increasingly used in men with non-metastatic prostate cancer. However, androgen deprivation therapy contributes to a decline in quality of life not only because of impaired sexual functions, but also because of physical function. There is evidence of loss in muscle strength and functional abilities. Effects on cognitive functions have been suggested but are less certain (reviewed by Alibhai *et al.*, 2006). In dogs, a role of castration in the development of cancer has been suggested. While some tumor types may be increased in castrated male dogs, others are decreased. In conclusion, in animals with a considerable life expectancy like companion

animals and horses, side effects of castration on general health and life quality cannot be excluded. This contributes to an ongoing discussion whether castration as a measure to improve manageability of animals can still be accepted. The risks and benefits of castration of an individual animal therefore have to be critically considered and discussed.

Surgical Castration

Orchiectomy is the oldest available and most common technique for castration of a male. However, it is a traumatic procedure, requires a qualified person and careful follow-up of the individual animal during the postoperative period to prevent complications. Main complications include excessive hemorrhage due to inappropriate crushing of the spermatic blood vessels, eventration (mainly prolapse of omentum or small intestine), inflammation, infection, and also myiasis. Secondary complications like funiculitis, sepsis, peritonitis, phimosis, or paraphimosis may occur.

In veterinary medicine, “open” and “closed” castration procedures are performed: “open” castration refers to a technique in which the inguinal tunic is incised for removal of the testis and epididymis but not sutured thereafter while “closed” castration includes procedures with suturing the inguinal tunic after removal of the organs. In animals, primary closure is rarely recommendable for castrations performed in the field. In contrast, when castration is performed aseptically in a surgical facility, advantages of primary closure include faster wound healing and thus earlier return to work (e.g., in male dogs and horses). Depending on size and age of the animals, castration may be performed with the animal standing while sedated and local anesthesia applied (e.g., in stallions) or in lateral or dorsal recumbency. In large animal species the spermatic cord is crushed with “emasculators” or similar instruments that help crushing and transecting the spermatic cord and *musculus cremaster* and thus reduce the risk of subsequent hemorrhage.

To avoid creation of an open wound, alternative “bloodless” surgical procedures causing loss of testicular function have been developed. Such approaches very much depend on the anatomy of the male genital tract in the respective species. In ruminants, the bottle-like shape of the scrotum and location of the testes in a relatively large distance from the abdominal wall in comparison to other species allow for castration by crushing the spermatic cords with clamps (e.g., the Burdizzo clamp) or application of rubber rings at the scrotal neck. These will dramatically reduce the blood supply of the scrotal organs resulting in tissue degeneration (Bretschneider, 2005). Because gonadal steroids stimulate growth and increase feed efficiency in ruminants, there is some interest in males that are infertile but still produce testicular steroid hormones. Such a situation exists in cryptorchids and has been imitated surgically by shortening the scrotum to an extent that the testes are located in a near-inguinal position. Short scrotum bulls and rams, due to the anabolic properties of androgens (Fig. 1), are more similar to intact than castrated males in growth rate, carcass characteristics, and meat tenderness but have the advantage that their infertility simplifies management (Glimp et al., 1971). Nevertheless, with all these alternative surgical approaches, failure may occur and at least some animals do not become completely infertile. Due to inappropriate inhibition of blood supply, testicular and epididymal degeneration is sometimes incomplete or due to insufficient increase of temperature within the testes, spermatogenesis is maintained at least in parts of the testes (Fig. 2A and B). Such failure also depends on the age of animals at surgery with earlier intervention being usually more successful with the Burdizzo technique.

Chemical Castration

Chemical castration (chemocastration, chemosterilization) offers the advantages of a single, low-cost, and permanent treatment resulting in loss of testicular function. This may be an alternative to surgical castration in some circumstances, that is, in regions

Fig. 1 Plasma testosterone concentration (mean + SEM) from 8 to 40 weeks of age in male cattle after resection of the scrotum (SR), Burdizzo castration (BZ), orchidectomy (OR), or left intact as controls (CO; $n = 10$ per group). Significant differences BZ and OR vs. SR and CO at all times ($P < 0.05$), significant difference over time ($P < 0.05$). Adapted from Pieler, D., Wohlsein, P., Peinhopf, W., et al. (2014). Endocrine testicular function and spermatogenesis persist in calves after partial scrotal resection but not Burdizzo castration. *Theriogenology* 80, 1300–1306.

Fig. 2 Testicular tissue of male cattle after Burdizzo castration. Tissue was collected at 40 weeks of age, Burdizzo castration was performed at 8 weeks of age. (A) Testicular tissue with heterogeneous atrophy with some tubules exhibiting full spermatogenesis including elongated spermatids (arrow). In other tubules variable degrees of atrophy were present (arrowhead). HE, bar = 100 µm. (B) Complete loss of testicular tissue and replacement by fibrous tissue with few mineralized foci (arrow). This tissue is surrounded by a fibrous capsule most likely representing the tunica albuginea (arrowhead). HE, bar = 100 µm. From Pieler, D., Wohlsein, P., Peinhopf, W., et al. (2014). Endocrine testicular function and spermatogenesis persist in calves after partial scrotal resection but not Burdizzo castration. *Theriogenology* 80, 1300–1306.

where cutaneous myiasis can complicate surgical treatment. Other complications like herniation or excessive hemorrhage are also avoided by this technique. The procedure requires only light or no sedation, pre-surgical preparation, and postoperative care. Chemical castration is therefore advantageous in regions where financial resources for population control are limited. A variety of chemical substances has been used for chemocastration. These include cadmium, calcium chloride, chlorhexidine, formalin, lactic acid, ethanol, zinc, and many others. These substances are injected into the testes and will induce tissue destruction, sclerosis, and subsequent loss of testicular function. The response may sometimes be incomplete. Also, considerable pain and discomfort in the post-operative period have been reported and scrotal fistulae may develop. It has also to be taken into consideration that chemicals like formalin or cadmium are not acceptable for the treatment of food producing animals. Recently, chemical castration in cattle has been performed with sodium chloride (20% and 30% solutions) to induce destruction of testicular cells by osmotic processes. This procedure was successful in calves at 20 days of age, but ineffective in calves near 5 months of age. Only minor signs of stress and inflammation were recorded (Oliveira et al., 2017). A variety of experiments on chemocastration by intratesticular injection of zinc-based formulations and calcium chloride in several species have been reported (reviewed by Cavalieri, 2017). Eventually, zinc gluconate has received US FDA approval as chemosterilant for use in male dogs in the United States and also some other countries (product name Zeuterin in the US respective EsterilSol in South America). Evidence of pain on injection as well as injection site reactions requiring treatment were reported in approximately 5% of cases. The underlying causes included necrotizing orchitis and scrotal ulceration. Treatment with zinc gluconate induced azoospermia in 80%–90% of treated dogs and 70% of cats, but for example not in adult bears. The great variation in the response rate to chemosterilants has been associated with differences in dose rates, concentrations, diluents, and injection techniques. The injection of excessive doses as well as inadequate restrained of animals results in loss of fluid from the testis into the scrotal space increasing the incidence of scrotal necrosis. Optimizing the procedure of injection may contribute to better effectiveness and reduction of side effects. However, effectiveness of treatment very much depends on testicular size and age of animals with the response being less successful in animals with larger testes because larger testicular size will prevent effective contact of chemosterilants with the majority of testicular tissue (reviewed by Cavalieri, 2017).

Hormone-Based Immunological Castration (Immunocastration)

Immunocastration is the stimulation of endogenous antibody production against hormones which are obligatory for successful reproduction by vaccination. The vaccinated individual becomes infertile for as long as sufficient antibody titers are present. The effect may be reversible or permanent. Hormones which have been targeted for immunocastration in males are gonadotrophin releasing hormone (GnRH) and follicle stimulating hormone (FSH). In humans, the development of contraceptive vaccines was initiated because of the sustainable rise in the worldwide population providing additional family planning options. In animals, immunocastration vaccines have been developed for limiting fertility in feral, livestock, and also companion animals (Bradley et al., 1999). It has to be considered that for the limitation of fertility in populations, the demands for efficacy, and controllability of such a treatment are lower than for the management of individual fertility. For free-ranging species, a long-lasting immune response in a high percentage of the target population is desirable. Present vaccines are unlikely to simulate a sufficient immune response in every individual and the duration of infertility is highly variable. These problems question the application of immunovaccination for management of individual fertility where precise predictability of treatment efficiency and maintenance is highly desirable. In humans, the potential use of GnRH vaccines for immunocastration is further complicated because subsequent supplementation of androgens is necessary for maintenance of secondary sex characteristics and libido. Nevertheless, immunization against GnRH has been considered an alternative for the treatment of androgen-dependent prostatic cancer and benign prostatic hypertrophy in men. A vaccine (Gonadimmune) has been developed but has not been commercialized so far.

In domestic animal species, active immunization against GnRH has recently gained practical significance. Despite the fact that passive immunization might be more selective, reproducible, and precisely timed, the method is at present not applicable for use in animal production systems because of the short maintenance of antibody titers. GnRH itself is too small to be immunogenic. Active GnRH vaccination therefore involves the injection of a GnRH analog which is conjugated to a foreign protein (carrier protein) and combined with an adjuvant. Vaccination induces the formation of anti-GnRH antibodies which inhibit the action of endogenous GnRH. The immune reaction may differ considerably among species and also among individuals within a given species. These may at least in part be overcome by adaptation of the vaccination scheme and of the adjuvant. Adverse effects such as excessive wound swelling or the development of persistent granulomas at the injection site or even pyrexia may occur but also seem to be associated with the adjuvant.

In bulls, active immunization against GnRH has been applied with the aim to reduce aggressive behavior. Because the carcass quality of bulls is superior to that of castrated males, it was also determined if GnRH immunization may be advantageous in comparison to surgical castration with regard to weight gain and meat quality not only in bulls but also in rams and bucks. In small ruminants, the reduction of male odor in meat has also been considered. Different vaccines and vaccination schemes have been used. GnRH immunization generally reduced LH secretion, but effects on testosterone concentration, behavior, and carcass characteristics were not consistent (reviewed in [Bonneau and Enright, 1995](#)). Therefore, GnRH immunization may be an interesting approach for castration of ruminants, but a more predictable response would be desirable. Nevertheless, for immunization of heifers, a GnRH vaccine (Vaxstrate) has been commercialized.

In young intact male pigs, GnRH immunization is by now routinely used as an effective method for inhibition of genital tract development, reduction of gonadotrophin and testosterone release, decreasing fat androstendione levels and the incidence of boar taint ([Bonneau and Enright, 1995](#)). GnRH vaccines for pigs have already been commercialized. Improvac, a vaccine against boar taint which has been developed in Australia and produced by Zoetis is approved in > 60 countries. A modification of the vaccine, Equity (Zoetis) has been commercialized as an oestrus control vaccine for horses in Australia and New Zealand; however, it has also been used for the immunocastration of adult stallions. Both vaccines, Improvac and Equity, differ with regard to the adjuvant. They both have to be injected twice with an interval of at least 4 weeks before efficient antibody titers are developed. However, in pigs, immunocastration is usually performed at an early age and a short-lasting effect is sufficient. The first injection of Improvac is usually given at an age of 17–18 weeks or earlier, the second at 21–22 weeks and animals are slaughtered when 26 weeks old. This vaccination scheme results in an efficient inactivation of endogenous GnRH and elimination of boar taint, results are considered very consistent among individuals at slaughtering. In contrast, in stallions, where vaccination is mainly performed at a postpubertal or mature stage, the outcome with regard to suppression of male behavior, semen quality, and fertility is quite variable ([Janett et al., 2009](#)). If Equity is not available as is the case in Europe, Improvac can also be injected in horses. Both vaccines may result in a severe soft tissue reaction at the injection site and also general side effects like increased body temperature. More importantly, effects on future fertility of an individual stallion are not predictable and infertility may persist. For the transient castration of stallions with future perspectives as breeding sires, the treatment with Equity or Improvac is therefore questionable.

Interruption of the Hypothalamus–Pituitary–Gonadal axis

Exogenous steroid hormones inhibit GnRH and subsequent LH and FSH release by making use of the negative feedback mechanism of the hypothalamus–pituitary–gonadal axis. The supplementation of exogenous hormones can therefore suppress fertility. Also, sustained exposure to GnRH, its analogues or antagonists reduces GnRH-stimulated gonadotrophin secretion through GnRH receptor down-regulation, internalization, and signal uncoupling. These processes can be summarized as interruption of the hypothalamus–pituitary–gonadal axis. They are considered reversible and may result in transient reduction of testicular function in males; however, species-specific variation has to be taken into consideration.

In many species, such as dogs and horses, treatment of males with high doses of exogenous progestins impairs testicular function and semen quality through a negative feedback inhibition of LH release. Nevertheless, interruption of spermatogenesis does not reliably occur. Therefore, such treatment has not gained much practical consideration so far. In dogs, administration of exogenous androgens is more effective and results in a significant but transient decline in daily sperm output and sperm motility. Treatment with anti-androgens has less pronounced effects on spermatogenesis ([Kutzler and Wood, 2006](#)), but is an effective treatment for benign prostate hyperplasia in this species.

The development of GnRH analogues for transient suppression of fertility in domestic and wildlife animals has recently gained increasing interest. Eventually, a slow releasing implant containing 4.7 or 9.4 mg of the GnRH analogue deslorelin has been licensed in Europe for the induction of temporary infertility in adult male dogs and ferrets and has been commercialized (Suprelorin, Virbac). The implant has many advantages such as ease of use, biocompatibility, safety as well as long-term release of sufficient concentrations of the drug. In male dogs, the 4.7 mg deslorelin implant is efficient for suppressing fertility for approximately 6 months, the 9.4 mg implant for 12 months, however, with considerable variation among individual dogs. This variation is at least in part influenced by body weight. Repeated use is possible and provides a continuous period of suppression of gonadal function ([Trigg et al., 2006](#)). The implant is also effective for the treatment of benign prostate hyperplasia in dogs. For population control in wildlife canids such as for example coyotes, the suppression of testicular function of implants available at present is not long-lasting enough to be attractive. In other companion animal species, results were less convincing than in dogs. In adult male cats, treatment with the 9.4 mg deslorelin implant resulted in complete sterility not before 72 days after application ([Romagnoli et al., 2016](#)), but was not effective at all in rabbits.

The horse has long been suggested to be resistant against down-regulation of GnRH receptors at the pituitary level. Recently, prolonged release of deslorelin (2.2 mg implants) has been associated with increased interovulatory intervals in mares leading to the assumption that potent GnRH agonists may be capable of down regulating GnRH receptors in this species. Treatment of adult stallions with 4.7 mg deslorelin implants after a transient increase finally reduced testosterone concentration for 6 weeks (Falomo et al., 2013). Reversible down-regulation of the hypothalamic-pituitary-gonadal axis in mature stallions was also reported after treatment with the GnRH antagonist acyline for 50 days (Davolli et al., 2016). However, these treatments never resulted in complete infertility of stallions and only minor effects on male sexual behavior were reported. Nevertheless, the development of effective treatment protocols with GnRH agonists or antagonists may offer attractive approaches for transient suppression of testicular function in stallions.

Germ Cell Transplantation

Introduction

All stem cells share a common property, the ability to self-renew and the production of daughter cells that undergo terminal differentiation, by which the function of the tissue and organ are maintained. Both these characteristics must be demonstrated to unequivocally identify a cell as a stem cell; therefore, to assess the biological function of a cell of interest, cell transplantation to a recipient is required. A large number of studies on hematopoietic stem cells and pluripotent stem cells, including embryonal carcinoma cells, embryonic stem (ES) cells, and induced pluripotent stem (iPS) cells, have been carried out since the 1950s, because these cells had functional assay systems based on cell transplantation to assess their biological functions. Until the early 1990s, most other tissue stem cells could not be unequivocally identified because a transplantation system was not available to evaluate their ability to self-renew and terminally differentiate.

The role of germ cells is to transmit genetic information to the next generation for continuity of the species. The process of male germ cell production, spermatogenesis, is a complex and highly productive system, because after puberty spermatozoa are continuously produced in the testis from SSCs that are the foundation of this highly productive system. A germ cell transplantation technique that allows identification of SSCs was developed in 1994, which was a major breakthrough for basic research and for translational/clinical use of male germ cells. In this article, the basic procedure of germ cell transplantation and application of the germ cell transplantation technique, including a quantitative SSC assay are described. In the last section, potential clinical applications using the transplantation technique and SSCs are discussed.

Basics of Germ Cell Transplantation Method

Outline of Germ Cell Transplantation Method

A technique for the transplantation of testicular germ cells into seminiferous tubules of recipient males was developed using mice (Brinster and Avarbock, 1994; Brinster and Zimmermann, 1994). The basic procedure consists of three parts: preparing a recipient male mouse prior to transplantation, preparing a testis cell suspension containing SSCs from a fertile male mouse (Fig. 1A and B), and microinjecting the cell suspension into the seminiferous tubules of an infertile recipient mouse (Fig. 1C). Two months after transplantation, donor-derived spermatogenesis is reconstituted from the transplanted SSCs, which continue to produce spermatozoa throughout the remaining life of the recipient (Fig. 1D). The recipient males will become fertile if sufficient SSCs are transplanted, and the males will generate progeny with donor haplotype following mating to wild type females (Fig. 1E and F). Long-term maintenance of spermatogenesis can be achieved only by SSCs capable of undergoing self-renewal and constant generation of daughter cells that differentiate into spermatozoa. Therefore, the germ cell transplantation technique established a mechanism to transfer SSCs from one male to another and to generate functionally normal spermatozoa derived from donor SSCs, resulting in production of progeny carrying the donor haplotype.

Preparation of Recipients

For efficient colonization of donor cells, endogenous germ cells of recipient mice must be depleted. It is important for the SSC niche, which is the microenvironment supporting self-renewal of SSCs (Oatley and Brinster, 2012), to be empty for efficient donor SSCs colonization of the recipient testis seminiferous tubule basement membrane. Appropriate recipient mice can be prepared by injection of Busulfan, which is an alkylating agent and used as an anti-cancer chemotherapy drug, to eliminate SSCs and other endogenous germ cells. One month following Busulfan injection most endogenous germ cells have disappeared, and these mice can be used as recipients. Mice with a congenital defect in germ cell development are an alternative to Busulfan-injected mice. The white spotting (*W*) mouse that has a mutation in the *Kit* gene, which encodes a receptor tyrosine kinase essential for primordial germ cell (PGC) proliferation and spermatogonial differentiation, is one of the best recipients for germ cell transplantation (Brinster and Avarbock, 1994). In addition, immature testes before forming the blood-testis barrier of Sertoli cells, which occurs between 10 and 16 days post-partum in the mouse, showed a higher efficiency of colonization of donor SSCs. The blood-testis barrier of Sertoli cells consists of tight junctions between Sertoli cells that allows passage of only small molecules and separates the seminiferous tubule into the adluminal compartment containing the differentiated stages of germ cells from the SSCs, which in contrast are exposed to all blood and lymph constituents. Other congenital germ cell-defective mice caused by spontaneous, targeted, or induced mutations can be used as a recipient if they have no defect in the microenvironment for spermatogenesis, such as in the SSC niche, secretion of differentiation factors, or the architecture of seminiferous tubules (Brinster, 2002). A drawback to the use of mutant mice is that they are often more difficult to maintain in sufficient numbers for recipients.

Fig. 1 Outline of germ cell transplantation method. (A) A single cell suspension is prepared from the testes of a fertile male. (B) The cells can be cultured with appropriate conditions. (C) Cells are microinjected into the seminiferous tubules of an infertile recipient male. (D) SSCs colonize the basement membrane of the seminiferous tubules and generate donor-cell-derived spermatogenesis. When donor cells carry a reporter transgene (e.g., β -gal), colonies can be identified as blue stretches of tubule. (E) The recipient male mates to a wild-type female. (F) Progeny with the donor haplotype are produced. Modified from Brinster, R.L. (2002). Germline stem cell transplantation and transgenesis. *Science* 296, 2174–2176. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

Preparation of Donor Cells

The donor cell sample should be prepared as a single cell suspension by enzymatic digestion of testis tissues and then introduced into the seminiferous tubules through a micropipette (Brinster and Zimmermann, 1994). Testis tissue from late fetal stages to old adults can be used as donor tissue/cell sources. PGCs and gonocytes, also called prospermatogonia or prespermatogonia, which are precursors of SSCs in embryonic, fetal and neonatal testes, can colonize recipient testis following transplantation, differentiate to SSCs, and reconstitute donor-derived spermatogenesis. Donor cells derived from transgenic mice that express a reporter gene, such as *lacZ* for β -galactosidase (β -gal) or *gfp* for green fluorescent protein (GFP), are useful because donor cells can be unequivocally identified in recipient testes by visualizing the reporter gene products (Fig. 1).

Cell-Injection Methods

Three different methods to introduce donor cells into seminiferous tubules of recipient mice were developed (Ogawa et al., 1997). The first method is the injection of cells directly into the seminiferous tubule using a micropipette (Fig. 2Aa). This method is the most direct way to introduce germ cells into seminiferous tubules. Donor germ cells are forced into the rete testis from the injected tubule and can then enter other seminiferous tubules because all seminiferous tubules are connected by the rete testis, from which spermatozoa normally are transmitted to the epididymis and then to the vas deferens for ejaculation. The cell suspension entering the rete testis can fill several other seminiferous tubules by retrograde flow. The second method is to insert a micropipette directly into the rete testis and fill the seminiferous tubules (Fig. 2Ab). The third method is to insert a micropipette into one of the efferent ducts, which connect the rete testis to the epididymis, and thread the pipette into the rete testis (Fig. 2Ac). This method is the most accurate for controlling the injection volume because less cell suspension leaks from the insertion site of the micropipette, and a larger number of tubules are filled with the injection suspension. Addition of a small amount of trypan blue to the donor cell suspension facilitates monitoring tubule filling (Fig. 2B). Normally, 70%–90% of the seminiferous tubules can be filled by injecting 4–10 μ L of cell suspension depending upon the size of recipient testes. All three methods have been used for mice and resulted in successful reconstitution of donor spermatogenesis.

Regeneration Process of Donor Spermatogenesis

The reconstitution process of donor-derived spermatogenesis by transplanted SSCs can be investigated using transgenic mice expressing β -gal (Nagano et al., 1999). When donor testis cells from these mice are microinjected into the lumen of the seminiferous

Fig. 2 Three cell-injection methods into a recipient testis. (A) The micropipette can be inserted directly into the seminiferous tubules (a), into the rete testis (b), or into an efferent duct (c). (B) A micropipette was inserted through an efferent duct. Recipient seminiferous tubules were beginning to fill by injecting donor cells with dye (trypan blue). Modified from Ogawa, T., Arechaga, J.M., Avarbock, M.R. and Brinster, R.L. (1997). Transplantation of testis germinal cells into mouse seminiferous tubules. *The International Journal of Developmental Biology* 41, 111–122. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

tubules of an infertile recipient male, some donor germ cells reach the basement membrane passing through the blood-testis barrier of Sertoli cells in the opposite direction of normal spermatogenesis (Fig. 3A). After colonization, the donor cells begin proliferating laterally on the basement membrane during the first month and then gradually differentiate toward the lumen (Fig. 3B). By 1 month following transplantation, donor-derived spermatocytes appear in the adluminal compartment of the seminiferous tubules. By 2 months after transplantation, donor germ cells fill the tubules, and spermatozoa begin to appear (Fig. 3C and D). Although the process of spermatogenesis from spermatogonia to mature spermatozoa in mice is reported to be 35 days, nearly twice as long is necessary to produce donor spermatozoa following transplantation (Brinster, 2002). The reasons for the difference of 35 days versus 2 months remains unclear, but migration from the lumen to the basement lamina, entering the SSC niche, and proliferation laterally, are likely involved in the time to produce mature spermatozoa following germ cell transplantation. In addition, the 35-day spermatogenesis time reported is measured from A1 spermatogonia, and the time for differentiation from an SSC to A1 spermatogonia is unknown and may account for a significant part of the additional 1 month for transplanted SSCs to produce spermatozoa. Following the first initiation of spermatogenesis at 2 months post-transplantation, the area of donor-derived spermatogenesis continues to extend laterally along recipient seminiferous tubules for a variable time but does not generally fill the entire length of the tubule (Fig. 3C and D).

Application of Germ Cell Transplantation Technique for Stem Cell Research

Functional Assay for Spermatogonial Stem Cells

The germ transplantation procedure has established a quantitative assay for identification of SSCs. When donor cells from a transgenic mouse expressing any visible reporter gene, such as β -gal, GFP, or other fluorescent protein are transplanted into recipient testes, donor-derived spermatogenesis is unequivocally identified 2 months after transplantation. When β -gal-expressing germ cells were transplanted, donor-derived spermatogenesis was identified as blue colonies after staining with X-gal, which identifies β -gal activity (Fig. 3D). These colonies are each derived from a single donor cell; hence, the number of blue colonies represents the number of SSCs in the cell suspension microinjected that could find an SSC niche and produce spermatogenesis. The colonization efficiency of SSCs transplanted into adult recipient testes is approximately 10% (Nagano, 2003); therefore, the actual SSC number in a donor cell suspension has been suggested to be 10-fold greater than the colony number. The factors responsible for the low colonization efficiency are not clear, but the necessity to migrate in the opposite direction of normal spermatogenesis between Sertoli cells, spontaneous differentiation before reaching the SSC niche, and passing through the blood-testis barrier are possible reasons.

Fig. 3 Regeneration process of spermatogenesis derived from donor SSCs expressing β -gal. (A) One week after transplantation, some blue cells were observed on the basement membrane. (B) Two weeks after transplantation, spermatogonial spreading with chain formation was observed. (C) Two months after transplantation, dark blue colonies with full spermatogenesis were identified. Donor cell-derived colonies continued to grow at the extremities. (D) Two months after transplantation, spermatogenic colonies derived from donor SSCs were identified as blue stretches of tubules under lower magnification. Each blue spermatogenic colony in the recipient testis is developed from a single donor SSCs. The testes were stained with X-gal. Scale bars: (A–C) 100 μ m, (D) 2 mm. Modified from Nagano, M., Avarbock, M.R. and Brinster, R.L. (1999). Pattern and kinetics of mouse donor spermatogonial stem cell colonization in recipient testes. *Biology of Reproduction* 60, 1429–1436. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

Although the original estimate for the number of SSCs in an adult mouse testis was approximately 20,000–35,000 based on morphometric criteria (Kubota and Brinster, 2006; Ogawa et al., 1997), the functional SSC number estimated by the transplantation assay is 3000, which represents 0.01% of all seminiferous tubule cells (Nagano, 2003).

When fluorescent protein-expressing cells are used for the donor source, repopulated donor SSCs can be recovered for further biological investigation by noninvasively identifying and recovering the spermatogenic colonies in the recipients. In addition, donor-derived post-meiotic germ cells can be used for round spermatid injection (ROSI) or intra-cytoplasmic sperm injection (ICSI) to produce offspring carrying the donor haplotype (Yanagimachi, 2005). Development of the functional assay system has resulted in enormous advances in understanding SSC biology and germ cell differentiation. Furthermore, the transplantation technique provides a powerful approach to study the SSC niche (Oatley and Brinster, 2012).

Functional Assay for Spermatogonial Stem Cell Precursors

In addition to providing a powerful means to identify SSCs in any donor cell suspension, the transplantation technique can identify precursor cells that are able to differentiate into SSCs. Gonocytes, which are the direct precursor of SSCs, are located in the center of seminiferous tubules of fetal and newborn testes and are mitotically inactive until the onset of spermatogenesis. In mice, gonocytes begin to proliferate and move to the periphery of the seminiferous tubules a few days after birth, and then they differentiate to SSCs. When gonocytes from fetal and newborn testes are transplanted into seminiferous tubules of mature testes, donor-derived spermatogenesis occurs, indicating that the donor gonocytes differentiated to SSCs in recipient mature testes. Furthermore, when PGCs, the precursor of gonocytes, and epiblast cells, the precursor of PGCs, were transplanted into immature testes, but not mature testes, before forming the blood-testis barrier of Sertoli cells, donor-derived spermatogenesis was reconstituted (Chuma et al., 2005). Therefore, the transplantation technique can be used for not only a functional assay to identify SSCs, but also to assess developmental potential of other cell types to produce SSCs. This ability has been applied to generate functionally normal spermatozoa from pluripotent cell lines, such as ES cells or iPS cells, without making chimeras. In a mouse model, epiblast-like cells were initially induced from pluripotent cells, and then further induced to form PGC-like cells. Following purification of the PGC-like cells, they were transplanted into the seminiferous tubules of immature *W* mouse testes. Donor-derived spermatozoa in the recipient testes were produced, and normal offspring were generated from the donor-derived spermatozoa after ICSI (Hayashi et al., 2011). To obtain functional gametes from pluripotent cells, the germ cell transplantation technique constitutes a final critical step and can be used as a functional assay to evaluate the quality of precursors of SSCs induced from pluripotent cells in culture.

Application of Germ Cell Transplantation to Various Mammalian Species

Application to Non-Rodent Species

The basic methods for spermatogonial transplantation in the mouse have been followed for all mammalian species, and the technique has been extended to many species, including other laboratory rodents, farm animals, companion animals, and primates (Brinster, 2007; González and Dobrinski, 2015) (Table 1). The procedure for non-mouse rodents, such as rat or hamster, is essentially the same as for mouse; however, some modifications for non-rodents are necessary because of species-specific anatomy of the testis, particularly size and testis rete structure. While there are three methods to inject donor germ cells as described above, donor SSCs in non-rodent species are introduced into the rete testis by ultrasound guidance or surgical dissection. Although Busulfan injection can be used for recipient preparation in non-rodent species, appropriate injection timing and doses for Busulfan must be determined in each species and is logistically difficult and inconvenient. Alternatively, local irradiation of testes has been shown to be effective for ablation of endogenous germ cells. Complete removal of endogenous germ cells is not essential, and residual endogenous spermatogenesis may be helpful to maintain a healthy testicular microenvironment to enhance donor spermatogenesis. In addition, immature males without pretreatment can be used as recipients of farm animals. In this situation, recipients with persistent endogenous spermatogenesis will produce both donor-derived and recipient-derived progeny; therefore, genotyping is necessary to determine the sire of each individual offspring. Furthermore, several experiments have indicated that donor germ cells from several species of farm animals were not rejected in MHC-incompatible recipients of the same species even without immunosuppressive treatments. This is strikingly different from laboratory rodents, which require immunosuppression when allogenic donor cells are transplanted. In goat and sheep, progeny with donor SSC-haplotype were successfully generated from immunologically incompatible recipients (González and Dobrinski, 2015) (Table 1).

Germline Modification Using Germ Cell Transplantation

An enormously valuable application of SSCs is for germline modification, also known as transgenesis (Brinster, 2002). The first transgenic animal using SSCs was created by transduction of a retrovirus vector containing the β -gal gene into mouse SSCs (Nagano et al., 2001). Although retroviral transduction was used in the initial approach, subsequent development of a long-term culture system now allows a variety of techniques to select successful modifications, resulting in generation of not only knock-out mice by homologous recombination (Kanatsu-Shinohara et al., 2006), but also gene-edited mice using the CRISPR/Cas9 system (Wu et al., 2015). In the mouse system, several methods for germline modification, including microinjection of DNA into the pronucleus, transplantation of pluripotent stem cells into blastocysts, viral injection into early embryos, and somatic cell nuclear transfer to enucleated eggs, have been developed (Behringer et al., 2014). Although pronuclear injection and pluripotent stem cell transplantation have been routinely used in the mouse until recently, germline modification in animals other than mouse was extremely difficult and inefficient. However, the development of the CRISPR/Cas9 system has enormously facilitated genetic manipulation of fertilized eggs and resulted in large numbers of transgenic animals in many species. In the CRISPR/Cas9 system with fertilized eggs, selection of correctly modified-embryos and avoidance of mosaicism containing both modified and

un-modified cells are major drawbacks. In contrast to fertilized eggs, SSCs can self-renew and replicate for long periods in vitro (Kanatsu-Shinohara et al., 2003; Kubota et al., 2004), which makes possible evaluation of both the correct genetic modification and expansion of the corrected cell type. In addition, SSCs can be cryopreserved for long periods (Avarbock et al., 1996), thereby permanently capturing and storing any genetic modification. Hence, genetic manipulation of SSCs by the CRISPR/Cas9 system with germ cell transplantation enables robust techniques for transgenesis in many species of animals without obvious drawbacks. In fact, the CRISPR/Cas9 system has now been applied to generate transgenic rats as well as mice (Chapman et al., 2015). The feasibility of correcting existing mutations by the CRISPR/Cas9 based-gene editing of murine SSCs has already been demonstrated (Wu et al., 2015). Similar approaches will be applied for a wide range of species not only to generate transgenic animals, but also to treat genetic disorders (Table 1).

Xenotransplantation

Following transplantation of rat SSCs into the seminiferous tubules of infertile immunocompromised mice, rat spermatogenesis was established in recipient testes (Clouthier et al., 1996) (Fig. 4A and B), and the rat spermatozoa in the mouse testes were functionally normal. The differentiation period from type A1 spermatogonia to mature spermatozoa is 52 days in rats and 35 days in mice. However, rat spermatogenesis occurring in mouse seminiferous tubules progressed at the rate found for rat spermatogenesis in rat testes indicating that the genotype of the germ cell, not the genotype of Sertoli cells or other environmental factors, controls the specific timing of spermatogenesis characteristic of each species. The result of rat to mouse transplantation experiments suggested that xenogeneic spermatogenesis might be reconstituted by transplantation of SSCs from different species into immunocompromised mice. However, when germ cells from various mammalian species, including rabbits, dogs, cats, pigs, cattle, horses, baboon, macaques, and humans, were transplanted into infertile immunocompromised male mice, complete donor-derived spermatogenesis did not occur, but primitive spermatogonia from all these species colonized and proliferated for 1–12 months on the basement membrane of the seminiferous tubules in immunocompromised mice (Brinster, 2002, 2007; Dobrinski et al., 2000; González and Dobrinski, 2015; Nagano et al., 2002) (Fig. 4C and D, Table 1). At present, the colony-forming spermatogonia in immunocompromised mice are believed to be SSCs and perhaps early undifferentiated spermatogonia. The remarkable results of xenogeneic transplantations indicate that factors produced in the mouse SSC niche can support proliferation of SSCs from many species.

Fig. 4 Xenogeneic spermatogenesis and spermatogonial colonization in nude mouse testes. (A) Four months after transplantation of rat testis cells expressing β -gal, rat spermatogenesis was reconstituted in the recipient mouse testis (blue stretches of tubules). The testis was stained with X-gal. (B) Histological analysis of rat spermatogenesis in the nude mouse testis 4 months after transplantation. The testis was stained with X-gal plus hematoxylin and eosin. (C) Six months after transplantation of porcine testis cells, clusters of porcine spermatogonia were observed. (D) One month after transplantation of human testis cells, clusters of human spermatogonia were observed. Germ cells in C and D were identified by species specific antibody staining and appear red. Scale bars: (A) 2 mm, (B–D) 50 μ m. Modified from Clouthier, D.E., Avarbock, M.R., Maika, S.D., Hammer, R.E. and Brinster, R.L. (1996). Long-term survival of human spermatogonial stem cells in mouse testes. *Fertility and Sterility* 78, 1225–1233. (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

Because the characteristics of the process of spermatogenesis are well conserved among mammalian species, conservation of self-renewing factors for SSCs and perhaps initial replication must be conserved as well. However, species variation in factors necessary for differentiation during spermatogenesis must exist among mammalian species. Sertoli cell transplantation from the same species as the donor germ cells may overcome the block in differentiation of xenogeneic donor germ cells in mouse testes. Transplantation of Sertoli cells, in addition to SSCs from xenogeneic species, might reestablish the necessary niche and differentiation factors for foreign species spermatogenesis in immunodeficient mice. It is extremely important to develop functional assays for non-rodent SSCs in which both self-renewal and differentiation can be evaluated.

Preservation of the Germline and Future Directions

Cryopreservation of Germline

Cryopreservation of SSCs from many species has been successful, and mouse SSCs can be cryopreserved for at least 14 years and, after thawing and transplantation, will regenerate spermatogenesis that produces functional spermatozoa (Avarbock et al., 1996; Wu et al., 2012). Thus, cryopreservation of SSCs provides an effective method by which to preserve the germline of individual males for long periods providing a potentially immortal lifespan for male germlines. Although semen cryopreservation is commonly used to preserve the germline of certain economically, biologically, or scientifically valuable males, including livestock breeds or endangered animal species, semen cryopreservation methods are complex and must be independently developed for each species. Thus, semen preservation techniques have only been developed for a limited number of species, but SSCs of many species are readily cryopreserved using procedures for somatic cells. Moreover, the number of SSCs can be increased in culture, and long-term culture techniques are currently available for several species (Kubota et al., 2011). Culture techniques for many valuable species, including human, livestock, and endangered animals will be developed in the future (Kubota and Brinster, 2006, 2008).

Clinical Applications of Germ Cell Transplantation

Functional spermatozoa can be obtained by transplantation of precursor cells of SSCs from immature males before puberty or even from fetuses, as well as from mature and aged males. Thus, an important, potential clinical application for human SSC transplantation is in prepubertal boys undergoing chemotherapy or radiation treatment for cancer (Brinster, 2007; Kubota and Brinster, 2006) (Fig. 5). Approximately 80% of childhood cancers can be cured, but SSCs and other germ cells are extremely sensitive to chemotherapeutic agents and radiation, resulting in nearly 1 in 5000 male cancer survivors of reproductive age being infertile or

Fig. 5 Clinical application of SSCs by germ cell transplantation. In prepubertal patients with cancer, SSCs could be isolated by testis biopsy before treatment with chemotherapy or irradiation and expanded in culture. The biopsy containing SSCs or expanded SSCs could be cryopreserved. After successful treatment, the SSCs would be transplanted to the patient's testes to restore fertility. For a patient carrying a genetic defect, the defective gene could be corrected in SSCs during culture. The SSCs with the corrected gene could be transplanted into the testes of the patient. Modified from Kubota, H. and Brinster, R.L. (2006). Technology insight: In vitro culture of spermatogonial stem cells and their potential therapeutic uses. *Nature Clinical Practice Endocrinology and Metabolism* 2, 99–108 and Brinster, R.L. (2007). Male germline stem cells: From mice to men. *Science* 316, 404–405.

extremely sub-fertile. While adults can cryopreserve semen before germ cell destroying therapies for future use in artificial insemination or in vitro fertilization, this option is not available for prepubertal boys because complete spermatogenesis has not been established. For prepubertal boys, cryopreservation of a testicular biopsy can be employed for future autologous transplantation into the seminiferous tubules following successful cancer treatment. The biopsy contains SSCs, which have the potential to colonize and restore spermatogenesis following transplantation. However, efficient culture methods to allow in vitro expansion of human SSCs are needed to increase the number of SSCs and eliminate potential cancer cells before transplantation of SSCs (Fig. 5).

Many genetic mutations causing human disease have been identified, and in the future, germline gene-editing may be considered for therapeutic correction. Once cultivation techniques of human SSCs become available, controversy will inevitably arise regarding the ethics of research designed to generate spermatozoa from gene-corrected human SSCs.

Concluding Remarks

Germ cell transplantation has revolutionized the study of the male germline of not only research species, but of all mammals, including companion animals, farm animals, endangered species and primates. Although the germ cell transplantation technique was originally developed in the mouse and allowed extensive characterization of murine SSCs, future studies will focus on a large range of species, including humans. Development of an efficient in vitro culture system supporting self-renewal and expansion of human SSCs and feasible germ cell transplantation protocols are critical to accelerate the advance of new medical applications and germ cell-based therapies.

MALE ENDOCRINOLOGY

Hypothalamic Pituitary Testis Axis

David Morritz de Kretser, Hudson Institute and Monash University, Melbourne, VIC, Australia

© 2018 Elsevier Inc. All rights reserved.

Understanding testicular function and the pathological states that result in male infertility or androgen deprivation requires knowledge of the hormonal control of the testis. The regulation of reproduction is under the control of the hypothalamic-pituitary gonadal axis. As early as 1930, the importance of the pituitary gland in controlling reproduction as well as many other functions was recognized (Smith, 1930).

Clear evidence for the involvement of this system also emerges from the seasonal influence on reproductive processes in females and males from many species but there is less evidence for a role of season in the control of human reproduction (Popa and Fielding, 1931; Harris, 1948; Green and Harris, 1951). These observations indicate that the changing day length is detected via the eyes and result in a change in reproductive behavior. In addition, the effect of psychological stress and marked weight loss associated with anorexia are known to influence the regularity of menstrual cycles. Further, as early as 1930 the need for replacement therapy following the removal of the pituitary was recognized (Smith, 1930).

The neural pathways involved result in stimulating the hypothalamus to send signals that act to alter the secretion of hormones from the pituitary gland that influence testicular and ovarian function (Popa and Fielding, 1931; Harris, 1948; Green and Harris, 1951).

As with all endocrine glands in the body, the endocrine control of the testis is exerted via the hypothalamic-pituitary testicular axis. The pituitary gland is formed by two components, one of epithelial origin from the developing pharynx which forms the anterior pituitary or adenohypophysis and a neural down growth from the hypothalamic region of the brain that forms the neurohypophysis (Figs. 1–4); (Popa and Fielding, 1931). The latter is responsible for the secretion of oxytocin and vasopressin.

Those signals are transmitted by peptide hormones that utilize a portal system of blood vessels to carry them from the hypothalamus to the anterior part of the pituitary gland (Fig. 4). In contrast, the posterior pituitary is composed of nerve fibers arising from nerve cells which release their products into blood vessels thus entering the circulation and transporting those entities to their sites of action (Green and Harris, 1951). Harris, one of the pioneers in this field articulated the basis of our current understanding of the physiology of the hypothalamo-hypophyseal system. He used electrical stimulation to demonstrate the neural link to the pituitary gland (Green and Harris, 1951).

The mechanisms involved are the secretion of gonadotropin releasing hormone (GnRH), a decapeptide secreted by hypothalamic neurones into the hypothalamo-hypophyseal portal vascular system that conveys the secreted GnRH to stimulate the gonadotrophic hormones, follicle stimulating hormone (FSH) and luteinizing hormone (LH) secretion by the gonadotrophin secreting cells in the anterior pituitary gland (Guillemin, 1964; Gersh, 1938). In turn, FSH and LH circulate in the blood stream to stimulate spermatogenesis and testosterone secretion by the testis in the male, and ovulation and estradiol secretion by the ovary in the female.

The pulsatile nature of LH secretion clearly supports the pulsatile nature of the GnRH stimulus but the pulsatility is less evident from the pattern of FSH secretion since the longer half-life of FSH obscures the pulsatility. The pulse frequency and amplitude is set

by signals from a collection of nerve cells in the hypothalamus called the arcuate nucleus. Thus external stimuli, such as the changes that occur due to seasonal alterations in photoperiod, are detected by the eyes and relayed to the hypothalamus. Therein, these visual stimuli are transduced into neural signals that are transmitted to pathways that affect the GnRH pulsatility. The latter, in turn, influence the secretion of FSH and LH by the pituitary. The early onset of pulsatile GnRH secretion results in precocious puberty whereas the failure to initiate pulsatile GnRH results in a delay or a failure to commence puberty in both males and females.

Modifications in the peptide structure of GnRH has resulted in some analogues having a higher affinity and high potency whereas other structural changes can result in agents that can bind to the receptor but fail to induce downstream signaling and can thus act as contraceptive agents.

As with most hormonal systems, the target tissue responds to the hormone and also sends feedback signals that modulate the bioactivity concerned. Thus the steroid hormones produced by the ovary and testis, estradiol and testosterone, exert a negative feedback action on the secretion of FSH and LH.

FSH also stimulates the ovary and the testis to secrete inhibin, a protein hormone that acts as its feedback regulator (Robertson et al., 1987). It is composed of two subunits termed α and β and specifically suppresses FSH and the DNA sequences for the encoding genes were cloned for bovine inhibin (Forage et al., 1986). A second protein that specifically suppresses FSH was also isolated (Robertson et al., 1987) and given the name FSH suppressing protein. The same protein was also isolated independently and given the name, follistatin, the name by which it is now known (Ying et al., 1987). Other agents such as neuropeptide Y enhance GnRH binding to its receptors and augment LH pulses. Immuno-neutralization of NPY attenuates the LH surge at ovulation. Similarly, the actions of estradiol on GnRH are complex, suppressing the magnitude in the first 36 h of exposure and then augmenting the response after 48 h.

Since the release of GnRH by the hypothalamus is pulsatile, the subsequent FSH and LH release by the pituitary is also pulsatile. The pulsatility is more evident for LH which has a shorter half-life than FSH. Through GnRH, which enables neural inputs into the regulation of the gonadotrophins, external factors such as photoperiod, nutrition, stress, infection, and inflammation can affect their secretory patterns. The arcuate nucleus, a collection of nerve cells or neurones in the hypothalamus, is responsible for setting the pulse frequency and amplitude of GnRH secretion. Thus the early onset of pulsatile secretion initiates precocious puberty and a delay in the onset results in delayed puberty. Some mutations in the GnRH receptor can negate the pulses of GnRH from influencing FSH and LH secretion and thus acting as a cause of the failure to initiate puberty.

The pathway controlling GnRH pulse frequency involves kisspeptin acting on the GPR-54 receptor on GnRH secreting neurones. In general kisspeptin and glutamate increase GnRH release and endogenous opioid peptides inhibit GnRH secretion. The actions of estrogenic steroids such as estradiol are complex with increasing levels being initially inhibitory and later stimulatory, in part dependent on the pulse frequency. As indicated above, the onset of FSH and LH secretion determines the timing of puberty in that an early onset results in precocious puberty and a failure or delay in the onset results in delayed puberty. In some instance, mutations in the genes encoding the GnRH receptor are the cause of the failure of FSH and LH secretion or result in low levels of these gonadotrophins causing delayed puberty or infertility. Mutations in the gene encoding this receptor are known to cause hypogonadotrophic hypogonadism which presents in males and females as the failure of pubertal onset. NPY is a 36 amino acid protein member of the pancreatic polypeptide family and enhances GnRH binding to gonadotrophs in the pituitary gland and augments the LH response to GnRH. In the testis, NPY expressing nerve fibers are confined to the capsule of the testis and capsular blood vessels (Allen et al., 1989).

Given that FSH and LH are the agents that circulate via the blood to the ovary and the testis, they are critical components that regulate spermatogenesis in males and oogenesis and ovulation in females. In turn, the ovarian and testicular steroid hormones, estradiol and testosterone, act predominantly as negative regulators of FSH and LH. In addition, FSH stimulates the gonads to produce a hormone, inhibin that acts as a specific inhibitor of FSH secretion. There are two forms of inhibin which are dimers of two subunits, alpha(α) and beta(β_A) and beta (β_B). Inhibin A ($\alpha\beta_A$) and Inhibin B ($\alpha\beta_B$) both suppress FSH secretion. Castration of males or females results in a rapid decrease in the serum inhibin levels indicating that the gonads are the source of these proteins. In the male, the Sertoli cells of the testes are the site of production of inhibin. There is yet another protein that regulates FSH and that is called follistatin which is structurally unrelated to the activins and inhibins (Meinhardt et al., 1998). In contrast to inhibin, the levels of follistatin did not change after castration, indicating that it was also produced at other sites.

There are also proteins that exert a stimulatory influence on FSH levels. These are dimers of the inhibin β_A and β_B units which can form proteins called activin A ($\beta_A\beta_A$) and activin B ($\beta_B\beta_B$) and stimulate FSH secretion (Vale et al., 1986; Ling et al., 1986).

Follistatin acts by binding the activins with high affinity and in vivo, the follistatin-activin complex is targeted to a lysosomal degradation pathway. Follistatin also binds to heparin sulfate proteoglycans that form part of the basement membranes of many tissues throughout the body. In addition to binding and inactivating the activins, follistatin also binds another protein called myostatin which, as its name suggests, is a "repressor" of muscle mass. Thus mutations of myostatin in cattle, which render myostatin inactive, have very large muscles as seen in the Belgian Blue breed of cattle.

The amino acid sequence of the activins and follistatin from rodents and humans is very highly conserved such that they are virtually identical. This degree of conservation across such a wide range of animal species suggests that these proteins have important functions.

Although, the activins are involved in the control of FSH, they are also regulators of our body's response to infection. Within 30 min of a challenge using lipopolysaccharide (LPS), a component of the *Salmonella* bacterium, activin A increases significantly (Jones et al., 2007). Other data available suggests that activin A is a major regulator of our body's inflammatory response. For instance, the levels of serum activin A and activin B are markedly elevated in patients admitted to intensive care units with acute

respiratory failure caused by a variety of agents (de Kretser et al., 2013) Should they remain elevated, they are indicators of a very poor outcome not just in the acute phase of the infection but also for up to a year after that hospital admission.

The outcome of inflammation in many organs is fibrosis or scarring and activin is responsible for the fibrosis and follistatin can be used to attenuate the degree of fibrosis.

While this section focuses on the male, these proteins have important regulatory functions in the female, covered in another section of this Encyclopedia of Reproduction.

The Gonadotropic System

The Gonadotropes

Gonadotropes are endocrine cells secrete LH and FSH located in the anterior pituitary. In the adult, they constitute 7%–15% of the anterior pituitary population (Moriarty, 1976). Importantly, studies have revealed 70% of the gonadotropes are bihormonal while 15% and monohormonal. These percentages can shift under different physiological conditions, such as castration or oestrous cycle (Moriarty, 1976).

Distribution of the Gonadotropes

Cells of the adult mammalian anterior pituitary were primarily described as part of the “diffuse endocrine system” (initially coined by Feyrter in 1938), with an appearing heterogeneous distribution of the different hormone-producing cells, however, studies over the last decade have challenged this concept in mouse models and demonstrated that the anterior pituitary consists of intermingled and highly-organized 3D networks of both endocrine and non-endocrine cells, including gonadotropes (Mollard et al., 2012). In the embryo, it appears that developing gonadotropes are initially organized in cell clusters in the central medio-lateral region of the anterior pituitary, with some isolated cells evident in more lateral regions (Budry et al., 2011). At birth the network of gonadotropes is organized as strings of cells extending from the ventral surface towards the center of the gland, with a second wave of gonadotropes appearing with the first 2 weeks postnatally on the dorsal surface, again organized as cell strings. At puberty and later on in adulthood, the network of gonadotropes is in close proximity with the pituitary microvasculature which ensures both the distribution of incoming GnRH towards gonadotropes and collection of secreted LH and FSH (Budry et al., 2011).

The Gonadotropins

The gonadotropins, LH and FSH are dimeric pituitary glycoprotein hormones have a common alpha and distinct beta subunit. The beta subunit confers unique biological activity on these hormones. LH and FSH appear to be packaged into different secretory granules when localized in bihormonal gonadotropes (Childs et al., 1986). After synthesis in the endoplasmic reticulum and passage through the Golgi apparatus, hormones are delivered to the plasma membrane through a constitutively or regulated secretory pathway; in the latter, fusion of secretory vesicles to the plasma membrane is arrested waiting for specific signals to be secreted (Durán-Pastén and Fiordeliso, 2013). The biosynthesis and secretion of LH and FSH is tightly regulated by counterbalancing positive inputs from the hypothalamus (GnRH) and negative feedback from the gonads (steroid and peptide hormones) as well as paracrine factors such as inhibins, activins, and follistatin (Durán-Pastén and Fiordeliso, 2013). Integration of these different regulatory signals by the gonadotropes results in the coordinated control of synthesis, packaging, and differential secretion of gonadotropins to accurately respond and control sexual maturation and normal reproductive function (Durán-Pastén and Fiordeliso, 2013).

GnRH Regulation of LH/FSH Secretion

Gonadotropins are released under the control of gonadotropin-releasing hormone (GnRH) (Iida et al., 1991; Leong and Thorner, 1991). This neurohormone is a decapeptide secreted in the portal blood by the GnRH neurons which are located in the hypothalamus. GnRH binds to its receptor that is located at the surface of gonadotropes and coupled to a G-protein system.

Several studies have shown that there is an absolute necessity of a pulsatile GnRH stimulus to sustain physiologic gonadotrope function (Belchetz et al., 1978). It is indeed possible to restore normal gonadotropin secretion with pulsatile GnRH administration in castrated monkeys bearing hypothalamic lesions rendering them hypogonadotropic, whereas continuous infusion of the peptide is completely ineffective (Belchetz et al., 1978). Similarly, in humans, continuous infusion of GnRH in normal subjects for prolonged periods first raises plasma levels of LH and FSH but this response attenuates after about 5 h and is completely lost after a few days (Gossage and Duncan, 1985). Those results indicate that continuous GnRH can result in a desensitization or down regulation of the processes responsible for gonadotropin release (Belchetz et al., 1978). The loss of the GnRH response with continuous treatment is known to be due to rapid uncoupling of the GnRH receptor from its intracellular signaling molecules (Adams et al., 1986; Tsutsumi and Webster, 2009). It has been showed that on one hand, continuous GnRH stimulation causes a transient increase in Gs/cAMP signaling that rapidly returns to baseline whereas Gq/11/DAG/Ca²⁺ signaling remains elevated during the entire period of GnRH stimulation causing a downregulation of receptor number. Pulsatile GnRH, on another hand, causes matching pulses of Gs/cAMP signaling of constant amplitude over time and Gq/11/DAG/Ca²⁺ signaling shows an initial pulse matching

but then feedback on itself so no further pulses are seen after 2 h, allowing a time locked regulation of LH pulses in response to GnRH pulses (Tsutsumi and Webster, 2009). Pulsatile stimulation with GnRH agonists can therefore be used to stimulate gonadotropin secretion, whereas sustained treatment ultimately reduces gonadotropin secretion, and this underlies GnRH agonist efficacy against steroid hormone-dependent cancers (Conn and Crowley, 1994).

Pulsatile Secretion of LH

In both males and females, secretion of LH and FSH is episodic, with secretory bursts that are mediated by a concordant episodic release of GnRH. The intervals between LH pulses in vivo range from 30 to 60 min in the gonadectomized rat (between 30 and 40 min), sheep (about 60 min), and monkey (50 min), with longer intervals reported in intact animals (Levine et al., 1982; Clarke and Cummins, 1985; Levine and Duffy, 1988; Terasawa et al., 1988; Goodman et al., 1995). Pulses of LH are characterized by their specific asymmetric shape with a fast increase immediately followed by a slower decrease, that is due to the clearance rate of LH from the blood. Overall, the intricate relationship between pulsatile GnRH release and secretory capacity of the pituitary gonadotropes generates the cyclic fluctuations in LH secretion.

Role of Calcium in GnRH-Stimulated Gonadotropin Secretion

Calcium Signaling in Gonadotrope Cells

Exocytosis in excitable cells is dependent on intracellular Ca^{2+} concentration. Gonadotropes, as other pituitary endocrine cells, display spontaneous intracellular Ca^{2+} transients dependent on changes in the membrane electrical activity (Leong and Thorner, 1991; Zemkova et al., 2006; Durán-Pastén and Fiordelisio, 2013). However, these membrane potential oscillations are small and do not produce the necessary intracellular Ca^{2+} increase to generate hormonal secretion (Tse et al., 1997; Stojilkovic et al., 2005). As a result, without extrinsic stimulus, basal secretion is low (Stojilkovic, 2006; Stojilkovic et al., 2005). In gonadotropes, the cytosolic Ca^{2+} levels regulate several maturation steps that secretory vesicles must undergo prior to fusion, like priming of secretory vesicles (Martin, 2003) but an entirely different phenomenon occurs when the intracellular Ca^{2+} concentration rises abruptly, and promotes the fusion of docked secretory vesicles with the plasma membrane. In contrast to nerve synapses, where intracellular Ca^{2+} influx is primarily responsible for this abrupt rise, exocytosis in gonadotropes is triggered to a large extent by calcium released from intracellular stores. Indeed, once GnRH binds its receptor, the α subunit of the G α q/11 protein dissociates and activates PLC- β , resulting in the hydrolysis of phosphatidylinositol 4, 5-bisphosphate (PIP2) and the production of two second messengers: diacylglycerol (DAG) and inositol 1,4,5-trisphosphate (InsP3). InsP3 binds to its receptor in the endoplasmic reticulum leading to oscillatory Ca^{2+} release and Ca^{2+} -dependent modulation of membrane electrical activity. Each Ca^{2+} elevation is in phase with membrane hyperpolarization, resulting in the opening of Ca^{2+} dependent SK-type K $^{+}$ channels (Kukuljan et al., 1997) and also Ca^{2+} channels (predominantly high-voltage-activated L-type calcium channels), allowing Ca^{2+} influx. Thus GnRH stimulates rapid Ca^{2+} mobilization from internal IP3-sensitive stores, followed by external Ca^{2+} influx. In most cases, the latest does not contribute to general Ca^{2+} elevation or gonadotropin secretion, but is crucial for refilling the intracellular Ca^{2+} pools (Stojilkovic et al., 1993).

Three different types of Ca^{2+} responses can be elicited in single gonadotropes depending on the concentration of GnRH: sub-thresholds, baseline oscillations and biphasic responses (Naor, 2009; Durán-Pastén and Fiordelisio, 2013). Subthreshold GnRH concentrations produce either small monophasic Ca^{2+} transients or irregular small Ca^{2+} spikes. With higher GnRH concentrations, large oscillatory Ca^{2+} transients are produced. Eventually these Ca^{2+} spikes fuse into an biphasic Ca^{2+} response which comprises two variants; biphasic oscillatory and biphasic non-oscillatory, also known as spike-plateau. It has been clear that different Ca^{2+} release patterns observed with increasing doses of GnRH underlie the dose dependent increase of gonadotropin secretion, but these different patterns also encode other cell functions. For instance, spike-plateau Ca^{2+} responses are associated to LH secretion and oscillatory Ca^{2+} responses to the synthesis of LH β -subunits (Naor, 2009). Whereas LH secretion is recreated in a pulsatile manner depending on GnRH stimulation; FSH secretion is mainly constitutive, thereby protein sorting domains in the β subunit of gonadotropins and the association with certain proteins may be responsible for differential sorting and packaging of LH and FSH into different secretory granules (Anderson, 1996).

Gonadotropin Exocytosis

Secretory granules containing LH and FSH must undergo a well-defined series of events: recruitment, tethering at the plasma membrane, priming, and vesicle fusion with the plasma membrane. Granules secretion in gonadotropes, as in other secretory cells, is a mechanism that uses the secretory vesicle synaptotagmin as a Ca^{2+} sensor and is mediated by SNARE (soluble N-ethylmaleimide-sensitive factor attachment protein receptors) proteins as effectors. Practically, synaptotagmin detects Ca^{2+} elevation and allows fusion of the gonadotropin-containing-vesicles to the membrane. Using electron microscopy, it has been showed that vesicles containing LH and FSH docks in a SNARE-depending manner into dedicated areas with diameter ranging from 100 to 500 nm whereas additional pores of 20–40 nm diameter have also been found, probably representing the constitutive pathway of gonadotropins (Savigny et al., 2007).

Transcriptional Regulation of Gonadotropins

Regulation of gonadotropins also occurs at the transcriptional level. The gonadotropins are composed of three subunits: a common alpha subunit that is similar in both LH and FSH, and a unique beta subunit that confers the biological specificity. The three subunits are encoded by different genes that are located on separate chromosomes and can therefore be differentially regulated. GnRH plays a major role in the control of the synthesis of the two gonadotropins, but it is by no means a sole factor. A complex interplay exists with other components of the HPG axis through feedback loops. Together, these combined factors allow the fine tuning of the transcription levels of the three subunits and hence form the basis of the ability of the pituitary to match its output to various reproductive states.

The Effect of GnRH

The transcription of the three subunits is highly sensitive to changes in the GnRH pulse frequency, and, to a lesser extent, the amplitude of the pulse. In males, rapid pulses (a pulse every 30 min) increase expression in both beta subunits, and more significantly of LH β , whereas slow frequencies (a pulse every 2–4 h) favor expression of the FSH β . Only the expression of the LH β is sensitive to changes in amplitude of GnRH pulses. The alpha subunit seems to be less responsive to changes in GnRH pulse frequency. The increase in transcript levels occurs within minutes after a GnRH pulse, but in order to sustain high transcription levels, subsequent pulses need to be present at the appropriate frequency (high frequencies will favor LH β transcription whereas low frequencies will enhance the transcription of FSH β).

The ability of the transcription machinery to respond to the changing pulse frequencies is mediated through the intracellular signal transduction pathways. Binding and activation of the GnRH receptor induces an increase of intracellular calcium as well as activation of protein kinase C (PKC). Both factors will act downstream through intermediate messengers to affect the synthesis of the subunit genes.

The calcium concentration in gonadotropes increases following activation of the GnRH receptor, both due to entrance of calcium through the plasma membrane and release from internal stores. This increase in intracellular calcium stimulates gonadotropin subunit transcription in a frequency-dependent manner, with higher frequencies increasing the expression of LH β and slower frequencies selectively enhancing FSH β transcription. These effects are mediated through the activation of calmodulin by the increase in intracellular calcium which in turn activates various second messengers that act at the nucleus to increase the transcription of the gonadotropin subunits in a frequency dependent manner (Melamed et al., 2012).

Calcium, along with PKC, also affect transcription through the mitogen-activated protein kinase (MAPK) pathway. The binding of the GnRH receptor activates PKC which, along with an increase in intracellular calcium, induces the activation of MAPK family of proteins that phosphorylate transcription factors that induce gonadotropin subunit synthesis. The activation of MAPK proteins is highly sensitive to pulsatile GnRH application and can therefore mediate the frequency of the GnRH pulsatility to the nucleus.

Gonadal Steroids

The gonadal steroids act as a crucial link between the gonad and the higher levels of the HPG axis, providing another pathway to differentially affect the synthesis of the gonadotropin subunits. The canonical pathway of steroid hormone action is through binding to steroid receptors which are then translocated to the nucleus and bind specific responsive elements in the promotor of genes, thus exerting their effect on gene transcription. In the male, circulating androgens affect the transcription of all three gonadotropin subunits. In general androgen can affect gonadotropin expression both through direct action on gonadotropes and through indirect action on the pulsatile secretion of GnRH. Androgens inhibit the expression of the alpha and LH β subunits. The exact mode of this inhibition is unclear as specific androgen-receptor responsive elements have not been identified in all LH β promoters studied and it is possible that the action is mediated by interactions with other transcription factors. Interestingly, in rodent models androgen directly interacts with the FSH β gene to up-regulate its expression.

Activin, Inhibin, and Follistatin

The FSH β gene is also under tight regulation by the activating-inhibin and follistatin hormones. While the full descriptions of these hormones are described in other chapters, it is important to mention them here briefly as they form part of the differential regulation mechanism of LH β and FSH β by exerting a specific control over the expression of the FSH β gene. Activins are critical regulators of FSH β transcription. They bind to specific receptors on the gonadotrope membrane and ultimately activate SMAD elements at the nucleus that specifically enhance the synthesis of FSH β . Follistatin, produced both by the pituitary and in the gonads binds activin, preventing the interaction to its receptor and thus acts as an inhibitor of FSH β expression. Inhibins, produced by the gonads, interfere with the binding of activin to its receptor and therefore inhibit its ability to induce FSH β expression.

Gonadotrope Interactions and Plasticity at the Level of the Gland

Apart from the intracellular level, the gonadotropes interact between each other within their 3D cell network organization. This highly organized structure suggests homotypic cell–cell interactions. This communication between gonadotropes is mediated

through gap-junctions (Göngrich et al., 2016) pore-forming proteins that can act to connect adjacent cells by allowing passage of small molecules such as calcium and other cellular messengers. This mode of information transfer along the gonadotrope network allows the pituitary to mount its typical large-scale hormonal response to hypothalamic stimuli.

Moreover, it has been demonstrated that both immortalized cell lines and cells in pituitary slices extend cellular processes and increase cell movement after GnRH stimulation (Bliss et al., 2007), and it is possible that this type of dynamic reorganization of the gonadotrope exists in vivo. In fact, this network remodeling may have a role in modifying the response of gonadotropes by changing the relationship of the gonadotrope network with the vasculature (Tibolt and Childs, 1985; Hodson et al., 2012) as gonadotropes were found to change their position relative to the vasculature in response to gonadal steroids (Alim et al., 2012).

Glossary

Activin Protein hormones/growth factors that are important in development and adult function. Member of the transforming growth factor-beta (TGFβ) family.

Apoptosis Tightly regulated cell suicide also called programmed cell death.

Azoospermia Lack of sperm in the ejaculate.

Hypophysectomy Surgical procedure to remove the pituitary gland.

Inhibin Protein hormone/growth factor related to activin.

Leydig cells Androgen-producing cells found in the testis interstitium.

Microarray Method for measuring the levels of large numbers of different mRNA transcript species.

Mitogen Factor that stimulates mitosis.

Oligospermia Low sperm concentrations in the ejaculate.

Sertoli cells Somatic cells which make up part of the epithelium of the seminiferous tubule and which regulate testis development and spermatogenesis.

Spermatid Male germ cell type that undergoes a differentiation process (called spermiogenesis) to form a spermatozoon.

Spermatocyte Male germ cell type that undergoes meiosis to form a spermatid.

Spermatogenesis Production of spermatozoa from spermatogonial stem cells.

Spermatogonia Basic male germ cell type which undergoes mitosis and is the engine driving the large number of germ cells formed in the testis. Differentiates into a spermatocyte during spermatogenesis.

Transcription factor Protein that controls the rate of DNA transcription to mRNA.

Introduction

Follicle stimulating hormone (FSH) is a protein hormone made up of two separate protein subunits, an alpha subunit (which is common to three different hormones: FSH, luteinising hormone (LH), and thyroid stimulating hormone (TSH)) and a beta subunit which is specific to FSH. The hormone is secreted into the blood by the gonadotrope cells of the anterior pituitary gland which is found at the base of the brain. Release of FSH is in response to stimulation of the pituitary by gonadotropin releasing hormone (GnRH) which is released from a regulatory part of the brain called the hypothalamus. In the adult female FSH is critical for ovarian follicle growth and without appropriate FSH stimulation an individual would not be fertile. FSH and LH (which is also released by gonadotrope cells) have evolved as separate hormones from a common ancestral hormone and it is likely that it was the needs of ovarian function in mammals that drove the evolution of two separate hormone (Huhtaniemi, 2015). In males, LH is known to be critical for the regulation of testis function and for fertility but the role that FSH plays is less straightforward and our understanding of the topic has undergone considerable revision over the years. This article will provide an examination of our current knowledge of FSH action largely derived from animal studies (rodents in particular) but also using examples from human and non-human primate research where relevant.

To understand the role of FSH in the male a knowledge of the cell biology of the testis is essential. Briefly, the testis is divided into two component parts (1) the seminiferous tubules (*red asterisk in Fig. 1A*) where germ cells develop from spermatogonia into mature sperm in a process called spermatogenesis and (2) the interstitial tissue (*green asterisk in Fig. 1A*) which lies between the seminiferous tubules. The interstitial tissue contains the Leydig cells (*red arrows in Fig. 1B*) which act primarily to secrete androgens (mainly testosterone). In addition to germ cells undergoing development (*black arrowheads in Fig. 1B*), the seminiferous tubules also contain the Sertoli cells (*blue arrows in Fig. 1B*) which have a primary role in testis development and function and act to maintain spermatogenesis (Rebourcet et al., 2014a,b, 2016; Smith et al., 2015). Spermatogenesis itself is divided into three phases; a proliferative phase where spermatogonia undergo mitotic division to increase their numbers and become spermatocytes, a meiotic phase in which the spermatocytes undergo a specialized type of cell division to become spermatids followed by a final maturation phase (called spermiogenesis) in which the post-meiotic spermatids undergo differentiation to form the mature sperm.

From a historical perspective, a role for FSH in male reproduction was first postulated in the 1930s by Roy Greep and colleagues although, at around the same time, it was also reported that LH could act to stimulate testis function and spermatogenesis. Subsequently, it was shown that LH acts on the Leydig cells of the testicular interstitial tissue to stimulate testosterone synthesis which, in turn, travels to the seminiferous tubules and stimulates spermatogenesis through actions on the Sertoli cells (Fig. 1C). The essential

Fig. 1 Testis morphology and interactions between different testicular cell types. (A) Low power micrograph showing a section through a mammalian testis. A cross section through a seminiferous tubule is labeled with a red asterisk while a representative section of interstitial tissue, found between different seminiferous tubules, is labeled with a green asterisk. (B) Higher power image showing interstitial tissue and the walls of different seminiferous tubules. Representative Leydig cells are shown with red arrows while Sertoli cells are shown with blue arrows. There are many different germ cell types in the walls of the seminiferous tubules and representative cells are identified with black arrowheads. (C) Schematic diagram showing interactions between the main somatic and germ cell types in the testis and how these interactions are regulated by the gonadotropins LH and FSH. The Leydig cells are stimulated by LH to produce testosterone and both FSH and testosterone act to stimulate the Sertoli cells. The Sertoli cells, in turn, regulate Leydig cells activity and stimulate germ cell proliferation and differentiation. Blue arrows show stimulation by known factors while green arrows show that the stimulatory factors are not known.

role of LH and testosterone in the control of spermatogenesis has been confirmed many times since these early studies but there is still debate about the role of FSH in testicular development and in adult testis function. In part this is because the importance of FSH may change as the animal or individual develops through puberty but, also, there are species differences in the significance of FSH in male reproduction. Finally, uncertainty about the role of FSH also arises because spermatogenesis is a complex process that is dominated by androgen action and it can be difficult to pick apart the effects of FSH from those of androgen. What is known is that FSH acts through specific receptors on the Sertoli cells, that it stimulates Sertoli cell function (at least at some points in development) and that it probably acts to optimize spermatogenesis and the number of mature sperm produced by the testis.

Control of FSH Secretion

In the male FSH secretion is regulated by GnRH from the hypothalamus, by locally produced activins and by androgens and inhibin secreted by the testis. Principal control is by GnRH which is released in pulses by the hypothalamus and so FSH (and LH) secretion is also pulsatile. This secretion from the pituitary is then modulated by the other factors. Activins produced in the pituitary act to stimulate FSH secretion but activin action is inhibited by testicular inhibin which prevents activin acting at its receptor. Inhibin is secreted by the Sertoli cells under the regulation of FSH and so this is a negative feedback mechanism that acts to maintain steady state (albeit pulsatile) levels of the hormone. Finally, testicular androgen acts to inhibit GnRH secretion from the hypothalamus and thus reduces FSH secretion by the gonadotrophs. FSH does not act directly to regulate androgen secretion by the testis but this is another pathway by which the gonads can regulate FSH secretion.

The FSH Receptor

FSH acts by binding to the FSH-receptor (FSHR) which is only found on the Sertoli cells in the testis and so all effects of FSH on spermatogenesis or on Leydig cell function must be mediated through the Sertoli cells. The FSHR is located on the plasma membrane and is a transmembrane G protein-coupled receptor with both an extracellular and intracellular component. Binding of FSH to the extracellular component of the receptor causes conformational changes which activate the intracellular part of the receptor. This activation leads to stimulation of the enzyme adenyl cyclase which also sits within the plasma membrane of the Sertoli cell. Activation of adenyl cyclase, in turn, catalyzes formation of the nucleoside cyclic AMP (cAMP) from ATP. This cAMP acts as a "second messenger" which causes further stimulation of intracellular signaling pathways and changes in cell activity and gene transcription (Smith and Walker, 2015).

FSH Effects on the Sertoli Cell

At a molecular level, changes in cAMP levels in the Sertoli cell caused by FSH binding to its receptor act to regulate up to five different signaling pathways in the Sertoli cells (PKA, ERK/MAPK, PI3K, Ca^{2+} , and phospholipase A_2 (PLA_2) pathways) leading to altered activation of gene transcription in the cells (Smith and Walker, 2015) (Fig. 2). Changes in gene transcription are brought about largely as a result of changes in the expression and activity of a number of transcription factors including CREB (cAMP response element binding) (Fig. 2). Activation of PLA_2 by FSH also acts to stimulate formation of prostaglandins in the cells which can act as intracellular signals or may be secreted by the cells (Fig. 2).

On a broader level, studies of how FSH regulates Sertoli cell activity have used a variety of methods including Sertoli cell cultures, treatment of animals lacking gonadotrophins (e.g., hypophysectomised rats which have had their pituitary gland removed or hypogonadal (*hpg*) mice which lack GnRH through a mutation) and, more recently, transgenic mice in which either the FSHR or the FSH β subunit has been knocked out (generating FSHRKO and FSH β KO mice respectively). In the FSHRKO and FSH β KO transgenic models, loss of the receptor or loss of the FSH β subunit means that there is no FSH stimulation of the Sertoli cell. Using these models a number of studies have tried to determine what effect FSH has on the Sertoli cell beyond stimulation of second messengers. Results show that, before puberty, FSH acts to increase general Sertoli cell activity by increasing cellular gene transcription and by regulating protein translation. In addition, FSH appears to increase the synthesis of a number of specific proteins such as androgen-binding protein, inhibin, androgen receptor, lactate dehydrogenase (LDH), kit ligand (KL), and glial cell line-derived neurotrophic factor (GDNF). Several of these proteins are involved in spermatogenesis (LDH controls the synthesis of the major fuel source for the germ cells, KL is involved in the survival and proliferation of the spermatogonia, transferrin transfers iron to the germ cells and GDNF is required for the self-renewal and survival of the spermatogonial stem cells in the seminiferous tubules) and this may be one of the ways in which FSH regulates spermatogenesis.

In addition to stimulating Sertoli cell activity, other studies using FSHRKO and FSH β KO mice have shown that FSH is essential for ensuring that the normal number of Sertoli cells form during development. Sertoli cell proliferation occurs primarily during fetal development in all mammalian species with a more species-specific pattern of development between birth and puberty. Near to puberty the Sertoli cells undergo a final differentiation stage in many species and cell proliferation stops. The number of Sertoli cells that form during development and that are present in the adult is important as it dictates both the number of germ cells that the testis can support and, probably, the number of Leydig cells which can form/survive in the adult (Rebourcet et al., 2014a,b). A decrease in either germ cell or Leydig cell number is likely to affect adult fertility and may have an effect on overall adult health through reduced blood levels of testosterone. The increase in Sertoli cell number during fetal/post-natal development is regulated primarily through androgen action and insulin/IGF signaling with the stimulatory effects of FSH, in mice at least, confined largely to the period between birth and puberty. These post-natal effects of FSH on Sertoli cell proliferation in the mouse may be mediated through the ERK/MAPK pathway and appear to require active insulin/IGF stimulation of the cells. While the role of FSH in

Fig. 2 FSH-signaling pathways in the Sertoli cell. Binding of FSH to its receptor causes the receptor-coupled G protein (Gs) to activate adenyl cyclase (AC) leading to the formation of cyclic AMP (cAMP) from ATP. Increased levels of cAMP in the cell can then activate a number of different pathways leading to gene regulation and prostaglandin formation in the cell. These include (i) activation of protein kinase A (PKA) which can directly lead to increased phosphorylation and activation of transcription factors such as cAMP response element binding (CREB) protein, (ii) action through guanine nucleotide exchange factors (GEFs) to activate CREB via extracellular signal-regulated kinase (ERK) (iii) induction of phospholipase A_2 (PLA_2) and formation of prostaglandin E_2 (PGE_2). FSH stimulation also leads to Ca^{2+} influx into the Sertoli cells and increased intracellular Ca^{2+} can activate multiple downstream paths including phosphorylation of CREB. Adapted from (Walker, W.H. and Cheng, J. (2005) FSH and testosterone signaling in Sertoli cells. *Reproduction* **130**, 15–28. (c) Society for Reproduction and Fertility (2005). Reproduced by permission.

determining the final, adult Sertoli cell number may be relatively limited in the mouse, evidence from other species is less clear and it is possible that FSH is of greater importance. There is evidence, for example, that in the rat and human FSH may act to stimulate Sertoli cell proliferation during fetal development (Allan and Handelsman 2005).

Control and timing of the final Sertoli cell maturation phase around puberty is important as it leads to the cessation of cell proliferation and determines the final number of cells that will be present in the adult. A decline in FSH action may be involved but it is also clear that the process requires thyroid hormone (TH) and in animals or humans with low TH levels there is a delay in maturation and continued Sertoli cell proliferation. Conversely, high TH levels lead to early Sertoli cell maturation, a reduced period of cell proliferation and fewer cells present in the adult testis. Overall, the number of Sertoli cells that form during development depends on the actions of androgen, FSH, insulin/IGF, TH and, possibly, local activin production.

As the Sertoli cells undergo the final, pubertal maturation phase of development they appear to become less sensitive and less responsive to the effects of FSH. This decline is associated with an increase in levels of the enzyme phosphodiesterase which acts to degrade cAMP and, thereby, limit intracellular signaling. There may also be more specific changes to the different intracellular pathways (such as a decrease in the ERK/MAPK path) mediated, perhaps, by changes in Sertoli cell adhesion to the wall of the seminiferous tubule. Whatever the mechanism, it has been suggested that the loss of FSH-sensitivity in the Sertoli cells is linked to initiation of final differentiation—that is, a decline in the ERK/MAPK pathway and increased cAMP degradation leads to a cessation in proliferation and a commitment to differentiated function although what induces this change in sensitivity is not known.

FSH effects on spermatogenesis

During Development

Spermatogenesis in the adult is a continuous process with germ cells at all stages of development present in the seminiferous tubules at all times (Fig. 1). Males are born, however, with only immature germ cells present in the testis and during post-natal development, therefore, there is a stage at which the first complete progression of spermatogenesis takes place from spermatogonia through to mature spermatozoa (also called a spermatogenic wave or cycle). This first wave, which completes after the onset of puberty, differs in comparison to later waves in that many of the developing germ cells undergo apoptosis (regulated cell death) at the spermatocyte stage and this appears to be an essential event which allows subsequent spermatogenic waves to occur normally. Studies have shown that one of the effects of FSH is to limit the extent of germ cell apoptosis during the first wave and if FSH levels are reduced there is a significant increase in germ cell death which may have knock-on effects to reduce germ cell number in the adult.

In the Adult

While there is good evidence that FSH is required for normal initiation of spermatogenesis it is less clear whether it plays a major role in the adult. Study of FSHRKO and FSH β KO mice shows that in the absence of FSH stimulation complete spermatogenesis takes place in the testes but the total number of germ cells is reduced (O'Shaughnessy, 2014). In comparison, there is failure to complete spermatogenesis leading to infertility in animals lacking androgen receptors on the Sertoli cells. In both FSHRKO and FSH β KO mice there is a 50%–60% loss of germ cells with all three categories of cells (spermatogonia, spermatocytes, and spermatids) showing a similar drop in numbers (O'Shaughnessy et al., 2012) (Fig. 3). This suggests that FSH is acting early in the process of spermatogenesis, during the proliferative stage of the spermatogonia, and that the reduced numbers of the more mature cells in FSHRKO and FSH β KO mice is a consequence of reduced spermatogonial number. Proliferative rates of spermatogonia *per se* are reported to be normal in FSHRKO mice and so the effect of withdrawal of FSH action appears to be an increase in apoptosis of the developing cells. Further evidence for this comes from *hpg* mutant mice (animals lack both LH and FSH) which have been crossed with animals lacking androgen receptors in the Sertoli cells (to create *hpg*.SCARKO mice). These animals are particularly useful because it is known that FSH can indirectly stimulate androgen production by the Leydig cells which can make interpretation of the effects of FSH complex. In *hpg*.SCARKO mice, however, androgens cannot affect Sertoli cell activity and so we can study FSH effects directly. Treatment of these animals with FSH increases spermatogonial and spermatocyte numbers without inducing spermatid formation (this would be predicted as completion of meiosis requires androgen action) consistent with results from the FSHRKO and FSH β KO mice. Overall, data from knockout mice and earlier *in vitro* studies suggest that the effect of FSH in the adult is to increase Sertoli cell number in the prepubertal period, the total number of germ cells in the testis and the number of germ cells associated with each Sertoli cell. These effects of FSH are achieved by increasing the number of spermatogonia in the testis and by increasing the number of these cells that enter meiosis (Abel et al., 2008). Overall, the likelihood is that FSH acts as a survival factor for premeiotic germ cells, limiting apoptotic cell death, rather than as a mitogen which stimulates cell proliferation (Huhtaniemi, 2015).

While FSH is clearly required to optimize spermatogenesis in the adult, what is less certain, however, is whether the loss of germ cells in adult FSHRKO and FSH β KO mice is due to loss of FSH action in the adult or to abnormal germ cell death during the first spermatogenic wave with consequential effects for subsequent spermatogenesis. Early studies on the effects of FSH administration to rats deprived of LH and FSH as adults (e.g., through hypophysectomy) would suggest that FSH is required into adulthood to maintain spermatogonial numbers and that FSH effects are not limited to the first spermatogenic wave. There are, however, limitations to these types of study as it is difficult to achieve normal physiological concentrations of the hormones through hormone

Fig. 3 Cross sections from testes of adult normal, FSHRKO, SCARKO, and FSHRKO·SCARKO mice. Testes from the FSHRKO mice contained all stages of spermatogenesis, although germ cell number was reduced. In SCARKO mice, there was progressive loss of spermatocytes as spermatogenesis progressed and few spermatids were present indicating a block in meiosis. In FSHRKO·SCARKO mice, the tubules were of a much smaller diameter with Sertoli cells (black arrowheads) and smaller numbers of spermatogonia (red arrowheads) seen in the tubules. Spermatogonia entered meiosis but development stopped early in meiosis in most cells (yellow arrowhead). From (Abel, M.H., Baker, P.J. and Charlton, H.M. *et al.* (2008) Spermatogenesis and sertoli cell activity in mice lacking sertoli cell receptors for follicle-stimulating hormone and androgen. *Endocrinology* **149**, 3279-3285 with permission from the Endocrine Society.

treatment regimes. One interesting study which has not yet, as far as I am aware, been carried out would be to determine whether FSH-treatment of FSH β KO mice restores normal spermatogenesis although, as above, achieving a normal FSH profile would be difficult and it is not clear whether androgen levels would change. At a cellular level, the effects of FSH on spermatogonial numbers are likely to be mediated through stimulated synthesis of specific proteins in the Sertoli cells (such as GDNF).

With respect to FSH and spermatogenesis, data from the rat and the mouse appear to apply generally across mammalian species, but there is one notable exception, the Djungarian Hamster. This animal is a seasonally breeding rodent in which daylength affects gonadotropin secretion causing the testes to go through cycles of activity and relative quiescence. Out of season, spermatogenesis is suppressed but treatment with FSH alone will induce full recovery without stimulating androgen secretion from the Leydig cells (Lerchl *et al.*, 1993). Testosterone will synergise with FSH and increase sperm production in these animals but the predominant hormone regulating spermatogenesis is FSH in a mirror image of other species.

Interactions With Androgen

As discussed, data from FSHRKO, FSH β KO, and SCARKO mice show that in the adult male androgens are the major drivers of spermatogenesis with FSH required mainly to increase the number of germ cells going through the process. Data from mice lacking Sertoli cell receptors for *both* FSH and androgen (FSHRKO·SCARKO mice) suggest, however, that there are interactions between the effects of the two hormones and that these effects can be additive, synergistic or redundant (Abel *et al.*, 2008). This applies to the effects of FSH on both spermatogenesis and Sertoli cell activity. With respect to spermatogenesis, the total number of germ cells in the testis is more affected by the loss of both hormone receptors than either hormone receptor on its own. This effect appears to be synergistic, rather than just additive, as very few germ cells develop in the double knockouts (Fig. 3). The primary failure in animals lacking both FSHR and the androgen receptor is an inability to generate spermatocytes from spermatogonia indicating that both hormones are needed to optimize these early stages of spermatogenesis. In addition, there is some evidence to suggest that both FSH and testosterone act to stimulate spermiation which is the process by which mature spermatids are released from the Sertoli cells. Overall, it is thought that both FSH and androgen act as survival factors to maintain the appropriate balance between germ cell division and germ cell death during spermatogenesis (Huhtaniemi, 2015). The two hormones act together to ensure that optimal numbers of germ cells are able to complete the spermatogenic process.

Synergistic effects between FSH and androgens are also seen in the expression of some Sertoli cell mRNA transcripts. As an example, Musashi RNA-binding protein 1 (MSI1), which plays a central role in post-transcriptional gene regulation (ie regulation of mRNA transcript levels after transcription has occurred), is specifically expressed in the Sertoli cells in the testis and its expression

is unaffected by knockout of either FSHR or AR. When both are knocked out, however, there is a significant drop of more than 50% in transcript expression (Abel et al., 2008). In this case it means that both hormones act to stimulate MSI1, perhaps because of the importance of its expression, and an effect is only seen when the actions of both hormones are prevented.

FSH Effects on Androgen Secretion

Androgen levels in the male are predominantly controlled by the action of LH on the Leydig cells (Fig. 1). Nevertheless, there is also considerable evidence to suggest that FSH is able to stimulate androgen secretion by the Leydig cells, at least under some circumstances. Since FSHR are only found on the Sertoli cells, however, the effects of FSH on the Leydig cells must be indirect and mediated through the Sertoli cells. Initial reports of FSH action on the Leydig cells came from immature hypophysectomised rats (i.e., rats lacking LH and FSH) which showed an increase in testosterone production by the testes in response to treatment with FSH. A similar effect was subsequently confirmed in adult *hpg* mice treated with FSH and microarray studies showed that the effects of FSH on Leydig cell function could be seen within a few hours of the first treatment. This means that there is an acute responsiveness to FSH in these animals as the hormone must act (presumably) to stimulate Sertoli cell secretion of an active factor which then acts directly on the Leydig cells. The factor would be expected to be secreted as there is no direct contact between Sertoli cells and Leydig cells and a number of potential candidates have been described which can stimulate Leydig cell function directly (e.g., atrial natriuretic peptide (ANP), epidermal growth factor (EGF), and corticotropin-releasing factor (CRF)). It is not known, however, whether any of these factors are secreted by the Sertoli cells in response to FSH. To add to the uncertainty, the Sertoli cell-secreted factor also appears to act primarily to increase steroidogenic enzyme levels without stimulating androgen production directly and so factors which act directly on Leydig cell androgen production may not be of relevance. Finally, it is unclear what role this interaction between FSH, Sertoli cells, and Leydig cells plays in the normal control of Leydig cell function since effects of FSH are generally only seen in the absence of LH. It is likely that this will only be resolved once the identity of the Sertoli cell-derived factor that stimulates Leydig cell function is finally established. Other studies have shown that the Sertoli cells in the adult animal are essential for maintaining the Leydig cell population and, while this effect is unlikely to be directly dependent on FSH, it does emphasize the importance of the Sertoli cells in regulating Leydig cell action. It is clear, therefore, that identification of the active factors involved Sertoli cell/Leydig cell communication must be a priority for future studies of testis biology.

Role of FSH in Primates

Data described in the studies above comes mainly from rodent models because of the relative ease with which hormone levels can be manipulated in these animals. It is likely that the results are broadly applicable to other species (with the notable exception of the Djungarian hamster) and there have been a number of studies in the human and other primates that have highlighted the similarities, but also the differences, to the rodent models. For example, a number of human patients have been described with inactivating mutations in either the *FSHR* or *FSHB* genes. Men with inactivation of *FSHR* have reduced testis size and are subfertile but they are not azoospermic (i.e., they produce sperm) (Huhtaniemi, 2015). This phenotype is similar to the *FSHRKO* mouse suggesting that FSH in both humans and mice is not required for ongoing spermatogenesis but acts to ensure production of optimal germ cell number. Somewhat confusingly, however, three men with inactivating *FSHB* mutations have all been shown to be azoospermic (Huhtaniemi, 2015). The possibility exists that some of these men had other abnormalities which caused, or exacerbated, the lack of sperm production and so further study with more cases will be required to allow us to establish the role of FSH in human spermatogenesis. Evidence from other primates is also complex (Plant and Marshall, 2001) but favors the concept that FSH effects on spermatogenesis in man and monkeys are similar to those in rodents with the hormone acting as a survival factor to premeiotic germ cells.

Use of FSH to treat oligospermia in humans has produced variable results and may only be effective if patients are pre-screened to identify those who are responsive to FSH (Huhtaniemi, 2015). Interestingly, it has also been suggested that the levels of FSH currently used to treat oligospermic patients are not high enough and that using four times the standard dose may be able to stimulate full spermatogenesis (Huhtaniemi, 2015). This would suggest that full-stimulation of the Sertoli cells by either FSH or androgen is sufficient to ensure normal spermatogenesis and that this is achieved normally through a combined effect of FSH and androgen with androgen the more potent agonist.

What We Don't Know

We have learned much about the role of FSH in reproductive biology since its discovery in the 1930s. This is especially true of its effects in the ovary but we also now understand a great deal more about what FSH does in the male, particularly since the generation of transgenic mouse models. Nevertheless, it is clear from what has been described above that a number of questions about the effects of FSH and its mechanism of action in the male remain outstanding and a number of these are highlighted here:

*Is the loss of germ cells in the adult *FSHβKO* or *FSHRKO* mouse due to loss of FSH action in the adult?* One problem with conventional transgenic animals is that the animal develops as a fetus and neonate in the absence of the gene and protein of interest. As described

above, reduced germ cell number in the adult knockout mice may, therefore, be due to disruption to the first wave of spermatogenesis which occurs at puberty. What is needed is a transgenic mouse model in which the FSH β subunit or FSHR can be deleted specifically in the adult. There are transgenic techniques available now which allow the timing of gene knockout to be regulated using an external inducing factor and the most widely used of these factors is tamoxifen. Unfortunately, tamoxifen acts through interaction with the estrogen receptor and so, by itself, has marked effects on mouse testis structure and development. This means that these inducible systems are far from optimal for studies into testis function and, as yet, there are no animal models available which allow specific, adult knockout of FSH or its receptor.

Why do the Sertoli cells become refractory to FSH at puberty? After puberty Sertoli cells continue to express FSHR but their response to FSH is attenuated. Some of the potential intracellular mechanisms involved in this process are known (eg increased phosphodiesterase activity) but how and why the process is induced at all is unknown. Loss of sensitivity to FSH during this maturation phase may be important in limiting the potency of FSH as a spermatogonial survival factor.

How does FSH act as a spermatogonial survival/proliferation factor? Since FSH cannot act directly on the spermatogonia it must induce release of active factors from the Sertoli cells. A number of FSH-dependent Sertoli cell proteins have been identified but the nature of these factors remains unknown.

How does FSH act on Leydig cells and is it an important mechanism? As with the previous question, the identity of the FSH-dependent Sertoli cell factor or factors that regulate Leydig cell activity remains unknown as does its potential role in normal regulation of Leydig cell function.

What is the role of FSH in male primates? This question is discussed in some detail above but it is worth re-stating that, while most evidence suggests that FSH effects in primates are similar to those in rodents, there is sufficient contradictory data to mean the question remains unanswered at present.

LH and the Male

Introduction

The pituitary gonadotropin luteinizing hormone (LH) is the crucial stimulator of testicular steroidogenesis, in particular of testosterone (T) production, in the Leydig cells present in testicular interstitial tissue. LH and T form the functional backbone of the hypothalamic–pituitary–testicular (HPT) axis (Fig. 1), a regulatory circuit where LH stimulates T production, which reciprocally regulates LH secretion by negative feedback action. LH functions by binding to the LH receptor (LHR), a G-protein coupled receptor (GPCR), located on Leydig cell plasma membranes. LH secretion and T production start in fetal life, and the latter is responsible for masculinization of the male fetus. In humans, instead of pituitary LH, placental choriongonadotropin (hCG), an LH analogue, is responsible for fetal testicular stimulation. Following a short postnatal active period (minipuberty), prepubertal quiescence follows, and the HPT activity reawakens at puberty and persists for the rest of life, slightly diminishing in old age. We will review in this article the salient features the human and rodent HPT axis throughout an individual's life-span.

LH and hCG

LH and hCG, the third gonadotropin follicle-stimulating hormone (FSH) and thyroid-stimulating hormone (TSH) form the family of glycoprotein hormones. They are structurally similar dimeric molecules consisting of a common α -subunit (CGA) [92 amino acids (aa)] and a hormone-specific β -subunit (121 aa in LH β [LHB] and 145 aa in hCG β [CGB]) (Fig. 2). LH is produced by gonadotrope cells of the anterior pituitary gland and hCG by placental trophoblasts. LH and hCG have some differences in their aa sequence, in addition CGB has a 24 aa long C-terminal extension and is more heavily glycosylated than LHB (30% vs. 15%). The differences provide hCG with longer half-life (12–24 h vs. 20 min) and higher bioactivity than LH.

The CGA gene is located on chromosome 6q14.3 and the cluster of one *LHB* and six *CGB* genes and pseudogenes on chromosome 19q13.32. The crystal structure of deglycosylated hCG reveals the so-called “cysteine knot structures” that reminds growth factor-type signaling molecules, such as TGF β . Both LH/hCG subunits have an elongated shape, with two β -hairpin loops on one side of the central cysteine knot and a long loop on the other side (Fig. 2). Noncovalent interactions keep the subunits together, and the dimer is stabilized by a segment of the β -subunit that extends like a “seatbelt” around the α -subunit and is “locked” by a disulfide bridge (Fig. 2).

Fig. 1 The hypothalamic–pituitary–testicular (HPT) axis. The main hormones functioning in the HPT axis are depicted, including the effects of kisspeptin on GnRH secretion, GnRH on LH and FSH secretion, and their effects on testicular function, followed by negative feedback effects of testicular sex steroids and inhibin. *GnRH*, gonadotropin-releasing hormone; *KiSS1R*, kisspeptin receptor; *LH*, luteinizing hormone; *FSH*, follicle-stimulating hormone; *R*, receptor.

Fig. 2 Schematic 3D structures of LH (panel A) and LHR (panel B). In (panel A) *red color* depicts the α -subunit (CGA) and *green color* the β -subunit (LHB). The arrow points to the “seat belt” structure of the β -subunit, which stabilizes the dimeric structure of the hormone. The asterisks depict the carbohydrate moieties attached to the hormone molecule. In (panel B), the structure in the top part depicts the leucine rich repeats of the extracellular receptor domain, which forms the primary binding site of the hormone. The cylindrical structures in the middle of the picture depict the seven transmembrane domains of the receptor molecule. (Courtesies of Drs. J. Dias and E. Reiter).

LH Receptor (LHR)

Gonadotropin receptors (and TSHR) are sialoglycoproteins with structural similarity, belonging to class A of the large family of GPCRs (**Fig. 2**). The single-chain LHR of approximately 75 kDa size is composed of 675 amino acids and is subdivided into a long extracellular domain, a transmembrane domain crossing the plasma membrane as seven α -helices that are connected by three extracellular and three intracellular loops, followed by a short C-terminal intracellular tail. Multiple leucine-rich repeats in the extracellular domain form the site of ligand binding. Both LH and hCG bind in humans to the same LHCGR [the term luteinizing hormone/choriogonadotropin receptor (LHCGR) signifies that in humans both LH and hCG bind to the same receptor. An appropriate term in rodents is LHR because they do not produce chorionic gonadotropin (CG)].

The *LHR* gene is localized on chromosome 2p21. The first 10 exons of *LHR* encode the extracellular receptor domain, and the last long 11th exon the rest of the receptor molecule. Transcription of the *LHR* gene is subject to silencing and activation through epigenetic mechanisms and phosphorylation and dephosphorylation events, a variety of signal transduction pathways, and derecruitment of inhibitors ([Dufau et al., 2010](#)). The TATA-less and GC-rich minimal *LHR* promoter is about 175 bp long, and upstream there are several inhibitor regions. Several hormones regulate *LHR* expression, including FSH, prolactin, growth hormone, and IGF-1.

LHR Signaling

LH and hCG binding to the extracellular domain of LHR alters the tertiary structure of the transmembrane receptor domain locking it into an active conformation. It will thereafter be coupled to a stimulatory G protein (Gs) and activates adenylyl cyclase, and enzyme that converts ATP to cyclic adenosine-3',5'-monophosphate (cAMP), which forms the primary intracellular second messenger of LH action (**Fig. 3**) ([Ascoli et al., 2002](#); [Tremblay, 2015](#)). Thereafter cAMP activates several protein kinases (PK), the best known of them being PK-A. This and other activated protein kinases lead, through a cascade of regulatory events to functional responses including increased expression of steroidogenic genes. As information has accumulated, the simple cAMP and PK-A mediated Leydig cell activation, and termination of LH action by phosphodiesterase-catalyzed degradation of cAMP, has evolved into a complex network involving interplay of multiple ligands, receptors, signaling cascades, and transcription factors, as summarized in **Fig. 3**.

Fig. 3 Schematic presentation of the mechanisms involved in LH-stimulated steroid production in Leydig cells. Binding of LH and osteocalcin (Os) to their G protein-coupled receptors (LHCGR and GPCR6A, respectively) activates adenyl cyclase (AC) leading to cAMP/cGMP production (yellow stars). Intracellular calcium (blue circles) concentration also increases following activation of the ryanodine receptor (RyR) and the inositol triphosphate receptor (IP₃R) located in the endoplasmic reticulum (ER). Increases cAMP, cGMP, and Ca²⁺ levels activate various kinases including protein kinase A (PKA), protein kinase C (PKC), protein kinase G (PKG), extracellular signal-regulated kinases 1 and 2 (ERK1/2), Ca²⁺/calmodulin (CaM) kinase I (CAMKI). These kinases are then involved in the activation of several transcription factors (CREB/CREM, GATA4, cJUN). Expression levels of some transcription factors (NUR77, cJUN, C/EBP β) are also increased. This induces expression of genes involved in steroid hormone synthesis and leading to increased T secretion. Within the Leydig cells, the stimulatory pathways are inhibited via phosphatases such as MKP1 and MKP2, which dephosphorylate ERK1/2, and via the repression mechanism active in steroidogenic cells (box on the right). To prevent overstimulation, cAMP is degraded by phosphodiesterases (PDEs) into AMP, which in turn activates the AMP-activated protein kinase (AMPK). Activated-AMPK represses the expression of transcription factors known to stimulate steroidogenesis (NUR77 and cJUN) and activates the expression of repressors of steroidogenesis (cFOS and DAX1). Other repressors are also involved including SHP and ARR19. All together, these events lead to a reduction in the expression of steroidogenic genes and in steroid hormone production. From Tremblay, J.J. (2015). Molecular regulation of steroidogenesis in endocrine Leydig cells. *Steroids* 103, 3–10, with permission.

Leydig Cell Steroidogenesis

The cascade of steroidogenesis (Fig. 4) starts with phosphorylation of the steroidogenic acute regulatory (StAR) protein in mitochondria. Basal StAR expression is low, but it quickly responds to LH, stimulating transfer of cholesterol from the mitochondrial outer to inner membrane, a rate-limiting step in steroidogenesis. The first step of steroidogenesis is the conversion of cholesterol to pregnenolone in mitochondria, catalyzed by the cholesterol side chain cleavage enzyme (CYP11A1). Thereafter the steroid molecule is transferred to smooth endoplasmic reticulum, where it is metabolized further. In humans, androgen synthesis proceeds mainly through the Δ^5 pathway (pregnenolone $\rightarrow$ 17-hydroxypregnenolone $\rightarrow$ dehydroepiandrosterone $\rightarrow$

Fig. 4 The key steroid metabolic steps in the ovary and testis leading to formation of T and estradiol. The Δ^5 pathway, used by the human testis, is marked with *green arrows*, and the Δ^4 pathway, more important in rodents, with *red arrows*. The same enzyme with dual function, P450 17-hydroxylase/17,20-lyase catalyzes both 17-hydroxylation and ring D side chain cleavage in pregnenolone and progesterone. Apart from the interconversion of 17-keto and 17-hydroxy steroids all other reaction in the steroid metabolic pathway are irreversible. Multiple isoform of 17-hydroxysteroid dehydrogenase (enzyme 4), with differing substrate specificities, catalyze these reactions.

androstenediol $\rightarrow$ T), whereas rodent testes use the Δ^4 pathway (pregnenolone $\rightarrow$ progesterone $\rightarrow$ 17-hydroxyprogesterone $\rightarrow$ androstenedione $\rightarrow$ T).

The magnitude of the steroidogenic response to LH/hCG stimulation differs greatly between humans and rodents. Whereas hCG injection stimulates an acute 10–20-fold increase in rat and mouse serum T levels within 1 h, a similar injection to humans brings about a sluggish 30%–50% acute increase and a delayed somewhat higher twofold response 2–4 days later. The main reason for the difference is apparently the nature of T in circulation. In rodents it is mainly in free form or loosely bound to plasma proteins (albumin) and therefore rapidly eliminated and metabolized, whereas in humans about half of T is bound to (and buffered with) high-affinity to sex hormone-binding globulin (SHBG).

Feedback Regulation in the HPT Axis

Gonadotropin secretion, stimulated by hypothalamic gonadotropin-releasing hormone (GnRH), is kept in homeostatic balance by negative feedback effects from the testis (T and inhibin-B) (Fig. 1) (Goodman, 2015; Herbison, 2015). In primates, and possibly humans, androgens suppress LH synthesis primarily through action on the GnRH pulse generator, but inhibitory effects are also found at the level of pituitary gonadotropes, which effect requires conversion of T to estradiol. The feedback inhibition at pituitary level is more prominent in rats. The hypothalamic level inhibition of GnRH secretion in men can be achieved with both androgen and estrogen. Because GnRH neurons do not express androgen or estrogen receptors, their negative feedback action has to be indirect. Indeed, evidence is mounting that hypothalamic kisspeptin neurons do express these receptors and mediate the sex steroid suppression. The function of the male HPT axis is tonic with only negative feedback effects from the testes, as opposed to negative and positive ovarian feedback in females.

LH Action in the Male Throughout Life

The HPT axis has three active periods throughout life (Fig. 5). The first is in fetal life, the second after birth (these two phases are merged together in rodents), and the third phase starts at puberty and continues until old age. Two distinct populations of Leydig cells exist in the testes, that is, the fetal and adult populations (Teerds and Huhtaniemi, 2015). The former appear in fetal life and

Fig. 5 Function of the HPT axis throughout the life-span of a human male. The fetal and postnatal activity of T production is due to a fetal population of Leydig cells. Adult Leydig cells appear to the testis at puberty and persists with somewhat decreasing activity throughout the rest of life. In rat and mouse, the fetal and neonatal peaks of T production are merged together with peak activity a few days before birth.

disappear after birth. The latter appear at puberty and persist thereafter for the rest of life. We will next review the special features of HPT function throughout life.

Fetal Life

Fetal Leydig cell T production apparently begins autonomously, or at least independently of LH/hCG action, because T can be detected in human and rodent fetal testes before the onset of LHR expression (O'Shaughnessy et al., 2006; Teerds and Huhtaniemi, 2015). However, the peak of fetal Leydig cell T production, occurring on gestation week 13–14 in humans and embryonic (e) days 18–18.5 in mice and rats, is clearly under influence of gonadotropin action, that is, pituitary LH in rodents and placental hCG in humans. Although pituitary LH concentration starts rising in fetal circulation after gestation week 12, it is apparently of minor functional importance, because the concentration of hCG around the peak of T production is at least 10-fold higher (Fig. 5). Following the fetal peak of T and LH levels, they decline toward the end of gestation apparently reflecting the onset of negative feedback of placental steroid hormones.

The situation in rats and mice is different, because they do not produce choriongonadotropin. Furthermore, their masculinization in fetal life is normal in the absence of LH and LHR, which is explained by the promiscuity of rodent fetal Leydig cells to stimulation by numerous nongonadotropic endocrine and paracrine factors (Teerds and Huhtaniemi, 2015). Hence, while human fetal Leydig cell T production is critically dependent on hCG/LHR activation, the rodent fetal Leydig cells are only LH responsive, but not LH dependent.

Minipuberty

The next phase of testicular endocrine activity in humans, minipuberty, occurs after birth from the first postnatal week until about 6 months of age, with a peak between 1 and 3 months (Fig. 5), when serum T in the baby boys is in the adult male range (Kuiri-Hänninen et al., 2014). The mechanism for this HPT activation is apparently the elimination of the negative feedback of placental steroids on gonadotropin secretion at birth.

The biological activity of T during minipuberty has been questioned, because it occurs concomitantly with a clear increase of SHBG, reducing the proportion of biologically active free T. In agreement with this, no postnatal increase exists in salivary T levels, considered to reflect the concentration of free hormone in circulation. However, there are several signs of increased androgen action in baby boys, such as increased testicular volume and penile length, and increase in the number of testicular Leydig, Sertoli, and germ cells.

Inhibition of the postnatal HPT activity in nonhuman primates by orchidectomy or GnRH analogue treatment reduced testicular weight and penis length. More prolonged effects include delayed puberty, reduced sexual, and aggressive behavior in adulthood as well as some metabolic effects. In rodents the fetal peak in T during the latter third of pregnancy declines gradually until the 2nd week of postnatal life, thus reminding of human minipuberty. Inhibition of the postnatal HPT activity in male rats brings about ejaculatory impotence in young adult age, which gradually subsides as the animals grow older.

To conclude, minipuberty most likely has a role in the development of reproductive capacity. The postnatal T peak may have a role in “stabilizing” the male genitalia, but it may also have anabolic effects on body growth and development, as well as on neural and psychosexual development.

Prepuberty

This dormant period of the HPT axis between minipuberty and puberty is viewed to result from function of a neurobiological break imposed on the GnRH pulse generator (Plant, 2015). However, this period is not completely quiet, because some activity is observed in the form of low night-time secretion pulses of gonadotropins and low peaks of T, associated with sleep onset. The prepubertal testis produces small amounts of T, and testicular T production at this age is highly responsive to hCG stimulation. Hence, the prepubertal HPT quiescence is primarily due to the lack of gonadotropin secretion, and the Leydig cells are ready to respond once LH secretion begins. The minor T production of prepubertal boys is functionally insignificant, as evidenced by the lack of sex difference of serum T concentrations in prepubertal children.

In rodents, there is a gradual decline of T production during the 2–3 postnatal weeks until the nadir at week 3 (Tapanainen et al., 1984; O’Shaughnessy et al., 2006). The decline is due to decreasing gonadotropin levels and gradual disappearance of the fetal Leydig cell population. Therefore, no distinct quiescent period of the HPT activity is observed.

Puberty

The onset of puberty is triggered by release of the neurobiological break imposed on the GnRH pulse generator, which results in reawakening of the HPT axis (Plant, 2015). At least a decline of inhibitory signals (GABA, opiates) and amplification of the excitatory inputs (glutamate, kisspeptin), are involved in the increased frequency and amplitude of GnRH, and consequently of gonadotropin pulses.

During pubertal maturation, the small night-time secretory pulses of LH (mean levels $<0.1\text{--}0.2\text{ IU} \times \text{L}^{-1}$ and peaks up to $1.0\text{ IU} \times \text{L}^{-1}$) begin to increase and start being accompanied by increased T secretion (Mitamura et al., 1999). Circadian rhythm of the very low LH and T concentrations already occurs in prepubertal boys 3–5 year of age, at least 3 year before the onset of puberty, and an increase in LH secretion starts about a year before the first signs of puberty, which require sufficient increase in T secretion. While higher night-time LH secretion persists, LH peaks spread to the whole 24-h period. The lag time between the LH and T pulse shortens as puberty progresses from about 2 h to 10–30 min. The consequences of increased LH-stimulated T production triggers gradually the physical secondary signs of puberty. Now also the feedback regulation of LH secretion begins, and increased T production starts inhibiting LH secretion by suppressing kisspeptin and GnRH secretion.

The sequence of events is similar in rodents as in humans, when the pubertal reactivation of their HPT axis occurs at around 3 weeks of postnatal life (Tapanainen et al., 1984; O’Shaughnessy et al., 2006).

Adult Age

The adult human HPT axis is set at the level of maintaining LH concentration at around $2\text{--}9\text{ IU} \times \text{L}^{-1}$ and T at $10\text{--}30\text{ nmol} \times \text{L}^{-1}$. Secretion pulses of serum T after the LH pulses (average interval of 1–2 h) are inconsistent, apparently due to the sluggish acute response of human testicular steroidogenesis to gonadotropin stimulation, and to the buffering effect of steroid hormone binding to plasma transport proteins. In rodents, in particular mice, serum T concentration shows major (up to 100-fold) variation between sequential samples, apparently due to its presence in protein-unbound form.

T secretion has diurnal variation with higher concentrations present in the morning hours and a trough in the evening (Mitamura et al., 1999). Data on circannual rhythm are inconclusive. The daily production of T in a male is 6–7 mg; about 95% originates from the testes and the rest from peripheral metabolism of adrenal androgen precursors. Besides T the human testes store and secrete intermediates and metabolites of the steroidogenic synthetic pathway, and in particular their sulfate conjugates. The latter have no known hormonal function, and apparently represent storage and secretory forms. T is also metabolized in Leydig cells further to the more active androgen metabolite $5\alpha\text{-DHT}$ and the female sex hormone estradiol (Fig. 4).

The secretion of steroid hormones is considered a passive process due to their lipid solubility and easy transit through cell membranes. It is noteworthy that the concentration of T in the testis tissue is about 100-fold higher than in peripheral circulation. This high intratesticular concentration has been considered crucial for the maintenance of spermatogenesis, although ultimately it may reflect the fact that the testis is the site of T synthesis (Oduwole et al., 2014).

In circulation, only about 2% of T appears in free, that is, nonprotein-bound form, 44% is bound to SHBG and 54% to albumin and other proteins. The plasma level of SHBG is under endocrine regulation, increasing clearly by estrogen and upon aging, and decreasing somewhat by androgen, and strongly by obesity. If the HPT axis functions normally, changes in SHBG levels do not affect the level of bioactive androgens, since they are quickly compensated for by changes in set-point of the feedback regulation.

Treatment of healthy men with T suppresses LH, FSH, and intratesticular T while maintaining peripheral T action. This leads to severe suppression of spermatogenesis—to the extent that the treatment provides a successful means of male contraception. If such men receive LH or hCG injections, their spermatogenesis recovers qualitatively, due to the restoration of intratesticular T levels. However, sperm counts remain by about 50% reduced, meaning that the reinitiation of spermatogenesis is possible with T alone,

but its quantitative recovery also needs FSH. When FSH was added to the treatment, spermatogenesis was fully restored. Treatment of T-suppressed men with purified FSH was able to stimulate spermatogenesis, though not quantitatively, suggesting that the effects of LH/T and FSH are, at least to some extent, complementary.

Aging

There is a modest decline of the HPT function with age, amounting to an annual decrease of 0.5%–1.5% of serum T concentration in most studies (Huhtaniemi, 2014). Opinions about the clinical importance of this modest decline vary. In some men the decline is deeper, and for them a new syndrome [male menopause, male climacterium, andropause, viropause, male midlife transition, late-onset hypogonadism (LOH), functional hypogonadism, etc.] has been coined. T treatment is being widely marketed and prescribed for its treatment, but still largely without evidence-based proof of efficacy over risks.

The aging-related decline in HPT function has been under intensive investigation (Wu et al., 2010; Huhtaniemi, 2014). One important question is whether the changes observed are due to biological age or to other concomitant alterations, and potentially treatable and reversible. Indeed, 75% of aging men with symptomatic hypogonadism (i.e., subnormal serum T with specific symptoms) are overweight or obese, and their T production improves after weight loss, lifestyle modification, and proper treatment of comorbidities. Obesity-related hypogonadism is of the secondary hypothalamic–pituitary type (low T and low or inappropriately normal LH), whereas the minority, caused by old age, is of the primary type due to testicular insufficiency (low T, high LH). SHBG levels increase with aging and decrease with obesity, and therefore the two conditions influence free T concentration to opposite directions.

Histological findings provide proof for the hormonal findings (low T, high LH) on primary testicular failure with aging. When compared between 20–48 and 50–76 years the average total number of Leydig cells per testis decreases by 44%, despite largely persistent normal ultrastructure of many Leydig cells. In most men, the decreased Leydig cell number and steroidogenic capacity are compensated for by elevated LH secretion. When this compensatory response is exhausted, T begins to decline and hypogonadism ensues. Animal experiments have shown that impaired LHR function, possibly due accumulating load of free oxygen radicals with age, is an important cause for the impairment of Leydig cell steroidogenesis. There is *in vivo* evidence in humans on impaired responsiveness of aged Leydig cells to LH/hCG stimulation as an additional cause for their weakened steroidogenesis.

Animal experiments indicate diminished outflow of GnRH as the cause of suppressed LH and T pulses in aging males with more frequent and smaller LH pulse. T-clamp experiments have demonstrated that the pituitary sensitivity to secrete LH in response to GnRH is not altered with age.

Causes of the gonadotropin suppression in obese men are not known in details. Peripheral and central insulin resistance may be involved, causing the suppression in SHBG and consequently lower total T levels. Other factors include hypothalamic inhibition by proinflammatory cytokines (TNF α and IL-6) originating from adipocytes, and central nervous system endocannabinoids that can downregulate hypothalamic function. In addition, adipocytokines such as leptin and adiponectin have been shown to modulate GnRH and gonadotropin secretion. Conversely, the suggested role of excess of fat tissue-produced estrogens in reducing the GnRH-gonadotropin secretion has not been confirmed in men.

To conclude, it seems that the primary hypogonadism specifically associated with aging is due to impaired Leydig cell function, which reduces gonadal feedback and consequently increases LH secretion, whereby the hypothalamic–pituitary function remains largely unaffected upon aging. The other and more common functional type of hypogonadism associated, but not caused, by aging is due to obesity, and it is of the secondary type caused by impairment of gonadotropin secretion.

Pathophysiology of LH/LHR Action in Men and Mice; Lessons From LH Subunit and Receptor Mutations and Knockouts

Human mutations and genetically modified mouse models have brought important novel information about the function of the HPT axis and its disturbances (Narayan, 2015; Huhtaniemi, 2017). All gonadotropin subunit mutations detected are inactivating, but both constitutively activating and inactivating mutations have been detected in gonadotropin receptor genes. Animal models for each type of mutation have been produced. The following text summarizes the key findings on these nature- and man-made experiments.

CGA and LHB

No human mutations in CGA have been detected, for the obvious reason that they would interfere with the production of hCG, which would be incompatible for the maintenance of pregnancy. However, CGA knockout (KO) mice have been produced, which is possible because the mouse genome does not contain a gene for choriongonadotropin. The CGA KO mice are hypothyroid and hypogonadal, due to lack of TSH, LH, and FSH, but male fetal development and differentiation are unaffected, because mouse fetal Leydig cells can produce T independent of gonadotropin stimulation (see above).

Human *LHB* mutations have been described in six men. The men are normally masculinized at birth, because hCG is able to maintain normal stimulation fetal Leydig cell T production. However, they completely lack normal pubertal maturation in the absence of pituitary LH and its stimulation of postnatal Leydig cell function.

The *LHB* KO mouse is normally masculinized at birth because of the aforementioned promiscuity of fetal mouse Leydig cells to nongonadotropic stimulation. However, this response is lost in adult Leydig cells that are unable to produce T without LH stimulation. Hence the *LHB* KO mouse is a complete phenocopy of the cognate human mutation, with complete lack of postnatal male sexual development.

Activating *LHR* Mutations

The first mutations in the HPT axis discovered were the activating *LHR* mutations because of their dramatic phenotype: an early onset (0.5–3 years) familial male-limited precocious puberty (Fig. 6). In these patients a point mutation in the transmembrane domain of *LHR* renders the receptor protein into constantly active conformation without ligand. Altogether > 10 such point mutations have been described today. If untreated, puberty of the boys progresses rapidly, resulting in premature epiphyseal closure, and compromised adult height. Various antihormonal therapies are used for the treatment (medroxyprogesterone, ketoconazole, cyproterone acetate, anastrozol, bicalutamide) to reduce the premature virilization.

An activating *LHR* knockin mouse model has been recently reported with precocious puberty, Leydig cell hyperplasia, and elevated T levels at very young age. Later on the mice develop Leydig cell adenomas and disturbances in sexual function and hyperplastic changes in genital structures.

Fig. 6 Locations of the currently known mutations of human *LHR*. Red boxes indicate inactivating mutation and green circles activating mutations. The short lines across the peptide chain depict the exon boundaries. *Fs*, frame shift; *Ins*, insertion; *Del*, deletion; *Spl*, splice variants; *X*, premature stop codon. Huhtaniemi, I. (2017). Male hypogonadism resulting from mutations in the genes for the gonadotropin subunits and their receptors. In: Winters, S.J. and Huhtaniemi, I.T. (eds.) *Male hypogonadism: Basic, clinical and therapeutic principles*. 2nd edn., pp. 127–152. Cham: Springer.

Inactivating *LHR* Mutations

Because of multiple mechanisms of receptor inactivation, there is no preferred domain of inactivating mutations in *LHR*, which exist in all parts of the gene and include both point mutation and deletions (Fig. 6). The inactivating mutations vary in severity, with consequent variability of phenotype. The mildest form is hypospadias and/or micropenis (Leydig cell hypoplasia, LCH Type 2), and the total receptor inactivating form causes complete male to female sex reversal (LCH Type 1) due to near-total to total lack of Leydig cell T production and sexual differentiation both in utero and postnatally. The phenotype differs from the androgen insensitivity syndrome by the lack of pubertal breast development, which in the latter is possible through conversion of the normally produced T to estradiol. The testes of individuals with complete *LHR* inactivation are totally devoid of mature Leydig cells.

The *LHR* KO mouse phenocopies some, but not all, features of the respective human mutation. The differences in phenotype can be easily explained by differences in HPT function of the two species in early development. Unlike human males with *LHR* inactivation the KO males are normally masculinized at birth, because of the earlier mentioned mouse fetal Leydig cell promiscuity to nongonadotropic stimulation. This response is lost in adult Leydig cells, which explains why the *LHR* KO mice, as humans with similar mutation, lack pubertal maturation and testicular T production in adult age.

Concluding Remarks

The crucial role of LH stimulates T production in induction and maintenance of function of the male mammals is undisputed. Recent inactivating mutations in humans of *LHB* and *LHR*, as well as knockout models for the same genes, have strengthened this concept. Mouse models provide accurate phenocopies of human mutations and explain the mechanisms of species difference in the HPT function. As information about the role of LH in the regulation of testicular function increases it is expected that better diagnostic and therapeutic tools for male hypogonadism, as well as male contraception, will develop.

Inhibin and Male

David M Robertson, Monash University, Clayton, VIC, Australia; and University of New South Wales, Sydney, NSW, Australia

Structure

Inhibin A and B consist of two covalently linked subunits (α and either β A or β B subunits) which are produced as 50–60k precursor monomers to form covalently linked $\sim$ 110k dimers. Under the action of the protease, furan either intracellularly or following secretion, the α subunit is cleaved at one or two sites while β A/ β B subunits are cleaved at one site to form a range of processed and partially processed inhibin forms with molecular weights ranging from 30k to 60k. The α subunit in contrast to the β subunit is mono- or di-glycosylated. The β A/ β B subunits also form homo- and hetero-dimers called activin A,B and AB with the mature molecule ($\sim$ 30k) the major form secreted. Other activin forms are known (activin C,D,E) but the corresponding inhibin forms in mammals have not been identified.

The α and β B subunit genes are located on human chromosome 2 and the β A subunit gene on human chromosome 7. There is a high (85%) structural homology across species for each of the three subunits with 63% homology within species between β A and β B subunit sequences. Activin A in particular, shows a high degree of homology across species with a single amino acid difference across human, bovine, porcine, ovine and murine species (Walton et al., 2011).

Assay Methods

A number of biological and immunological methods have been used to quantitate inhibin. Inhibin was originally isolated employing in vitro bioassays using pituitary cells in culture with FSH release or cell content as the biological end point. Activins, conversely, stimulate FSH secretion from pituitary cell cultures but have also been found to exhibit mitogenic activity in a range of cell systems including the testis. Enzyme-linked immunoassays (ELISAs) have been developed for inhibin A and B using paired antibodies directed to the α and either β A/ β B subunits. ELISAs to the α subunit (using antibodies directed to NH₂ and COOH-terminal regions (Pro- α C) have been devised which detects primarily the free α subunit in serum as inhibin precursor levels in serum are low. Non-specific inhibin assays have also been devised which detect all α subunit containing inhibin forms. These ELISAs have been widely applied to serum, gonadal extracts and cell culture media in a range of species. Many of these ELISAs are commercially available (Walton et al., 2011).

Isolation and Native Forms

Inhibin A was originally isolated from ovarian follicular fluid as both mature ($\sim$ 32k) and partially processed (58k) forms consisting of a dimer of mature β A and either processed or partially processed α subunit. These forms are bioactive based on their FSH suppressing activity. Inhibin A has been isolated from ovine rete testis fluid with a mol wt $\sim$ 30k consisting of a α and ovine β A sequence.

Inhibin B is the most common or abundant form of inhibin found in males in humans, non-human primates and rodents while inhibin A predominates in sheep but is also found in addition to inhibin B in bovine and porcine species. The 30k mature and partially processed 50–60k inhibin forms show similar in vitro bioactivities, however the unprocessed precursor inhibin form is bioinactive due to its inability to binding to betaglycan, a cofactor essential for inhibin's inhibitory activity. However the unprocessed precursor levels in human serum are minimal. A comparison of the in vitro and in vivo bioactivities of inhibin A and B in rats showed that human 30k inhibin B was $4.2 \times$ and $1.45 \times$ more potent than 30k inhibin A. The α subunit is bioinactive based on its FSH suppressing activity.

An assessment of molecular weight forms of inhibin B in human male serum shows a combination of mature (26–30k) and partially processed (60–65k) dimeric (α and β B) forms and an absence of inhibin A. In healthy men or men with testicular disorders, inhibin B exists in plasma as 29% precursor, 8% free α subunit and the remainder as the mature 30k form. The free α subunit exists as either the full α subunit precursor (49k) or predominantly as a partially processed molecule (29k) termed Pro- α C (Makanji et al., 2011).

Location and Production by the Testis

Following castration, inhibin diminish to nondetectable levels indicating the testis is the major source for inhibin, while activins levels remain unchanged indicating nongonadal sources. Inhibin α subunit (as mRNA or protein) is produced by the Sertoli and Leydig cells but not by germ cells. The β A subunit, as mRNA and as detected by immunocytochemistry has been detected in Sertoli and peritubular cells while β B subunit has been identified in the Sertoli cell, peritubular cells, spermatogonia, primary spermatocytes and round spermatids. In the rat, mouse, monkey and human, inhibin B only is synthesized primarily from the Sertoli

cell while the Leydig cell produces free α subunit and possibly some inhibin B. Leydig cell stimulation with human chorionic gonadotropin (a hormone with high luteinizing hormone activity) in humans resulted in an increase in free α subunit but no increase in inhibin B. Considering the high levels of activin A produced by Sertoli cells in these species, it is surprising that substantial amounts of inhibin A are not also produced. This incongruity suggests that α subunit dimerisation with either β A or β B subunits by the Sertoli cell is likely to be a regulated process with a preference in the formation of inhibin B rather than inhibin A in some but not all species.

Inhibin α subunit and to a lesser extent, β B subunit production by Sertoli cells *in vitro* are stimulated by FSH through the protein kinase A pathway. Earlier studies failed to detect FSH stimulation of β B subunit in Sertoli cells but this was established with more sensitive nuclear run-on or real time PCR methods. The expression of activins by germ cells is not thought to contribute to inhibin synthesis or inhibin formation by Sertoli cells. Immature Sertoli cells also produce β A subunit, but it is not normally stimulated by FSH.

The close relationship between Sertoli cell number, sperm number and serum inhibin B has been observed in the rat, monkey and human suggesting that inhibin B is a marker of Sertoli cell number and hence sperm number based on their close relationship. In the rhesus monkey, serum inhibin B correlated with both Sertoli cell number and testicular round spermatid number. This association is supported by studies showing that administration of GnRH or FSH to monkeys or to men with acquired hypogonadotropic hypogonadism led to an increase in inhibin B from undetectable levels into the normal range in parallel with the recovery of spermatogenesis. However, administration of FSH to men with normal spermatogenesis showed no increase in inhibin B despite an increase in serum inhibin α subunit. Inhibin B levels remained unchanged following LH administration. Thus inhibin production is linked to Sertoli cells number and the closely linked sperm number ([Hedger and Winnall, 2012](#); [Ramaswamy and Plant, 2001](#); [Sharpe et al., 1999](#)).

Role of Testicular Germ Cells

The α subunit, β B subunit and inhibin B show cyclic behavior across the spermatogenic cycle in rats peaking in Stages XIII–I of the cycle with lowest levels in Stages VII–VIII. This pattern parallels changes in FSH sensitivity in tubule segment cultures across the cycle. The β A subunit peaks in Stages VII–XII. This variation across cycle in inhibin B and α , β subunits suggests that their expression is modified by the stage of spermatogenesis and thus by particular germ cell types. To examine this further, α and β B subunit levels were monitored in rats following vitamin A deficiency and replacement where stages of spermatogenesis can be specifically investigated. Under these conditions, α and β B subunit levels decreased following Vitamin A deficiency but recovered with Vitamin A replacement in parallel with the recovery of spermatogenesis. It was concluded that inhibin B expression was stimulated by the presence of early spermatocytes and round spermatids while mid-pachytene spermatocytes exerted an inhibitory effect. Using X-irradiation to deplete the testis of spermatogonia and all subsequent germ cell types, resulted in inhibin B levels decreasing to non-detectable levels. Other procedures modifying germ cell number (chemotherapy, androgen treatment) also led to decreases in inhibin B. These studies suggest that a germ cell factor is influencing Sertoli cell production of inhibin B. Co-cultures of Sertoli cells and isolated germ cells have identified inhibitory effects on inhibin B protein and message however the factor(s) has not yet been identified ([Hedger and Winnall, 2012](#)).

An inverse relationship has been observed between serum inhibin B and FSH in normal men and men with testicular pathologies. Following chemotherapy and testicular irradiation, spermatogenesis including spermatogonia and inhibin B levels decrease to non-detectable levels while FSH reaches castration levels. With androgen treatment (e.g., in contraceptive trials), despite sperm number as well as serum FSH/LH decreasing to near non-detectable levels, serum inhibin B decreases partially, in some cases minimally, suggesting that serum inhibin B is only partially under gonadotropin control. As an explanation, it should be noted that the process of spermatogenesis is largely unchanged prior up to the spermiogenic stage by androgen antagonist treatment. However, subsequent stages associated with sperm release are inhibited by androgen antagonist treatment leading to the premature loss of round spermatids from the epithelium and a reduction in sperm release into the reproductive tract. Hence inhibin B production under the influence of early stage spermatogenesis can continue despite absence of sperm in the ejaculate ([De Kretser et al., 2004](#)).

Collectively, these data indicate that FSH stimulates Sertoli cell proliferation and inhibin B secretion in the pre-pubertal testis. Once spermatogenesis has been initiated, FSH stimulation of Sertoli cell number and sperm number ceases. Thus changes in inhibin B levels as a result of testicular damage or endocrine manipulation in the adult are related more to changes in germ cell composition and their influence on Sertoli cell inhibin production. Reductions in inhibin B prior to puberty are a reflection of reduced Sertoli cell number.

Changes With Age

Both α and β B subunits are localized to fetal human and rat Sertoli cells. Inhibin A and B are detectable in human male serum at 14–16 weeks of fetal life. In male fetuses at mid trimester, inhibin B levels correlate directly with LH and indirectly with FSH. Following birth, inhibin B and FSH are low until puberty when both increase between Tanner stage G1 and G2. Inhibin B falls with age in men, by age 70–85y inhibin B has fallen 25% while serum FSH increased fourfold. In rats and rhesus monkeys there is a prepubertal peak in inhibin B prior to the subsequent post pubertal rise. In rats but not humans, serum inhibin A is detected at low levels post birth peaking at day 15 then decreasing thereafter ([Itman et al., 2006](#)).

Action on the Pituitary

Exogenous administration of purified preparations of inhibin A and B to rats, monkeys and sheep have shown a selective suppression of FSH but not LH while active immunoneutralisation using antisera raised to the inhibin α subunit showed a rise in FSH. Further evidence was derived from endocrine manipulations of gonadotrophin secretion (e.g., following hemicastration and suppression of gonadotrophins by steroid treatment) and by review of serum hormone patterns associated with human testicular disorders. Inhibin's endocrine role was underscored in studies in mice where inhibin A was inducibly expressed and secreted by the liver. In both short and long term studies in which physiologic and high inhibin A serum levels were maintained, serum FSH, testicular size and seminiferous tubule volume were reduced in strong support of the endocrine role of inhibin in regulating FSH (Pierson et al., 2000).

While inhibin has been shown to preferentially reduce pituitary FSH production and secretion, activin in contrast, has been shown to preferentially stimulate FSH β subunit synthesis and thus FSH. Activin's action is mediated by binding to two pituitary receptor proteins in sequence, Activin receptor Type II (ActRII) and Type I receptor (ALK4) which in turn phosphorylates specific second messenger intracellular proteins (SMAD2/3) which migrate to the nucleus. Other SMAD proteins (SMAD 4/7) either inhibit or facilitate this transfer or interaction with DNA. Activin B in addition to that seen with activin A is thought to involve an additional Type I receptor (ALK7) which is known to phosphorylate SMADs 1,2,5.

Studies exploring the possibility that inhibin may exert its inhibitory actions by inhibiting activin's action through a specific receptor had been unsuccessful. Binding proteins for inhibin were identified but failed to mediate inhibin's action. Inhibin was able to weakly suppress activin's stimulation of FSH production and secretion. However its inhibitory activity was increased dramatically with the identification of a cell surface proteoglycan called betaglycan which bound inhibin, creating a high-affinity complex blocking the ActRII receptor site limiting the stimulatory action of activin. Betaglycan also interacted with other members of the TGF β superfamily for example, TGF β II where it is essential for activity, and BMP2,4,7. As pituitary gonadotrophs express α , β B and β B subunits as well as betaglycan and activin type 1 and 2 receptors why cannot locally produced inhibin be responsible for inhibiting activin's action on the pituitary? While this is possible, the bulk of the evidence supports gonadally produced inhibin as the major inhibin source (Bilezikjian et al., 2006; Lewis et al., 2000).

To differentiate between the contributions of inhibin and the reproductive steroids, testosterone and estradiol as endocrine hormones in regulating FSH, *in vivo* studies in men were undertaken using aromatase inhibitors, to suppress the conversion of testosterone to estradiol (a key steroid in regulating FSH and LH), and ketoconazole which suppresses testosterone and estradiol production. Inhibin B levels were marginally decreased (16%) while FSH levels doubled following treatment. In contrast, in men with anorchia (prepubertal testis) where inhibin B levels were low, FSH was markedly elevated to approach castrate levels. It was concluded that inhibin B was able to regulate or stabilize FSH secretion under normal circumstances but that once inhibin B levels fell below normal range values, the underlying stimulatory effects of steroids on FSH becomes apparent. These authors concluded that in the human male, inhibin B is the principal gonadal feedback regulator of FSH secretion unless seminiferous tubule function is severely compromised (Boepple et al., 2008).

Inhibin B has been detected in seminal plasma showing a wide range of concentrations. It correlates with sperm number in fertile and infertile men and is absent following vasectomy. However semen and serum inhibin B levels do not always correlate, for example, in progestin male contraceptive studies, semen inhibin B levels were non-detectable while detectable in serum and vice versa. The reasons are unclear (Anderson, 2001).

Over Expression and Deletion of Inhibin Subunit Genes

Mice with deletions of the α and β B subunit genes showed a loss of inhibin B with a corresponding increase in serum FSH. Deletion of the α subunit results in the development of testicular tumors by 4 weeks post birth attributed to the concomitant rise in the production of the β A/ β B subunits as activins A/B which are potent mitogens. Prior to tumor formation normal spermatogenesis was observed although FSH was elevated twofold over controls. Embryogenesis appeared to be normal.

In contrast, over expression of the α subunit led to decreases in serum FSH, testicular size and sperm production but the mice remain fertile. These decreases are attributed to a decline in activin production and its mitogenic effects upon the testis as a result of an increase in α : β subunit dimerisation due to the increase in α subunit production.

Deletion of the β A subunit gene is lethal at birth while deletion of the β B subunit gene and thus a loss of inhibin B, showed negligible effects on the testis and fertility in adult male mice. Overall these studies show an inhibitory endocrine role of inhibin on FSH levels but are complicated by the trophic effects of excess activin when the α subunit is deleted (Chang et al., 2002).

Clinical Relevance

The observed correlation between serum inhibin B, Sertoli cell number and sperm count has suggested that inhibin B may be suitable as a biomarker of testicular function. During infancy and childhood, inhibin B is a clinically useful marker of Sertoli cell function in boys with various testicular disorders (anorchia, abdominal testis and gonadal dysgenesis). In addition, inhibin B is a useful marker in the diagnosis of primary and congenital central hypogonadism where inhibin B and FSH are low and in acquired central

hypogonadism where inhibin B is normal. Inhibin B is also a useful marker of spermatogenesis in cancer survivors following radiation therapy and chemotherapy. In particular serum inhibin B is a predictive marker of azoospermia in boys and adult males treated for testicular cancer (Valeri et al., 2013).

Activins in Male Reproduction

Kate L Loveland, Hudson Institute of Medical Research, Clayton, VIC, Australia; and Monash University, Clayton, VIC, Australia

Discovery and Physiological Context: Activins are Central to Reproductive Health

Although the testis produces factors that can maintain secondary sexual characteristics in the absence of ongoing spermatogenesis, the pituitary-derived hormone, follicle stimulating hormone (FSH), is required to establish and maintain fertility. FSH levels are widely used to assess the reproductive health of males (Kelsey et al., 2017), and the extent of FSH synthesis and secretion reflects endogenous and environmental factors that control fertility.

The search for important cellular and biochemical elements that control reproductive health led to the isolation of inhibins and activins in the 1980s. Independent teams discovered activin as a protein present in ovarian follicular fluid that stimulates pituitary cell FSH secretion, placing activin in an important reciprocal relationship with the newly described inhibitor of pituitary FSH production, inhibin. The excitement these discoveries generated was fuelled by recognition that inhibin and activin are in the TGF β superfamily of over 30 ligands that signal through a distinct receptor class. Activin B was purified in 1992 and identified as the pituitary-derived activin moiety most likely to be driving FSH β subunit gene transcription in gonadotropes (reviewed in Fortin et al., 2015).

Assays measuring circulating activins and inhibins are now commonly employed along with FSH measurements to ascertain hypothalamic–pituitary–gonadal (HPG) axis function within individuals. Activins function as both endocrine and paracrine factors, being synthesized and acting directly on cells within many different organs, such as gonads, brain, bone marrow, adrenals, intestinal tract, as well as circulating widely to coordinate organ growth and homeostasis. Despite the important, diverse roles of activins and inhibins in human clinical issues, most knowledge of activin biology has been gained from studying animal models, especially rodents in which genetic modifications and culture methods permit functional pathway analyses.

Structural Features of Activins, Members of the TGF β Superfamily of Ligands

Activins Are Dimeric Ligands

The activins are classified as TGF β superfamily members, based on common ligand structure and shared signaling machinery usage. Five activin genes encode distinct β subunits: activin β A (e.g., *INHBA* gene, may also be termed inhibin β A), B, C, D, and E, with D not present in the mammalian genome. These form and function as homo- and heterodimers, with two β A subunits forming activin A, activin β A, and β B subunits forming activin AB, and activin B a dimer of two β B subunits, and four of these subunits collectively forming the signaling moiety (Fig. 1). Individual activin subunit genes and proteins are highly conserved, with mouse and human activin A mature proteins 100% identical, and human activin A and B 64% identical (reviewed in Loveland and Hedger, 2015).

Subunit Domains and Factors Affecting Ligand Functionality

Each subunit is synthesized with a proregion that directs entry into the endoplasmic reticulum during translation for eventual secretion, and pro- and mature-protein domains. Formation of the overall tertiary structure of activin signaling molecules is initiated by dimerization through a single intermolecular disulfide bond within the mature region. Proteolytic processing separates the pro- and mature domains. The proregion remains closely associated until the ligand is secreted; this noncovalent association is relatively weak for activin, enabling ready availability for receptor binding upon secretion. Proregions mediate formation of three intramolecular disulfide bonds within each mature signaling molecule (Harrison et al., 2011). The inhibin α subunit is produced in a similar way, but does not form homodimers. Instead, an α subunit pairs with an activin β subunit to generate a potent inhibitor of activin binding to its receptor. Inhibin A forms as an α : β A dimer and inhibin B as α : β B (Fig. 1). The stoichiometry of α and β subunits produced by each cell determines the relative levels of either activin or inhibin generated. Additional factors affecting activin bioactivity are specific proteolytic enzymes that separate the pro- and mature domains, pro-convertases (e.g., PCSK3, also named furin, for activin A). The activin proregion also affects ligand stability and binding to the extracellular matrix (ECM), in addition to its attainment of the tertiary structure required for signaling. Selective binding of activin to the heparin sulfate proteoglycan side chains of perlecan or agrin (Wang et al., 2016) may also increase its local concentration or mediate its presentation to the receptor to initiate signaling.

Activin Signaling Mediators and Regulators

Activin Signaling

The TGF β superfamily ligands constitute a unique class of molecules that signal through cell surface receptors with intracellular serine/threonine kinase activity. Activins first bind a Type II receptor subunit which contains a constitutively active kinase, typically

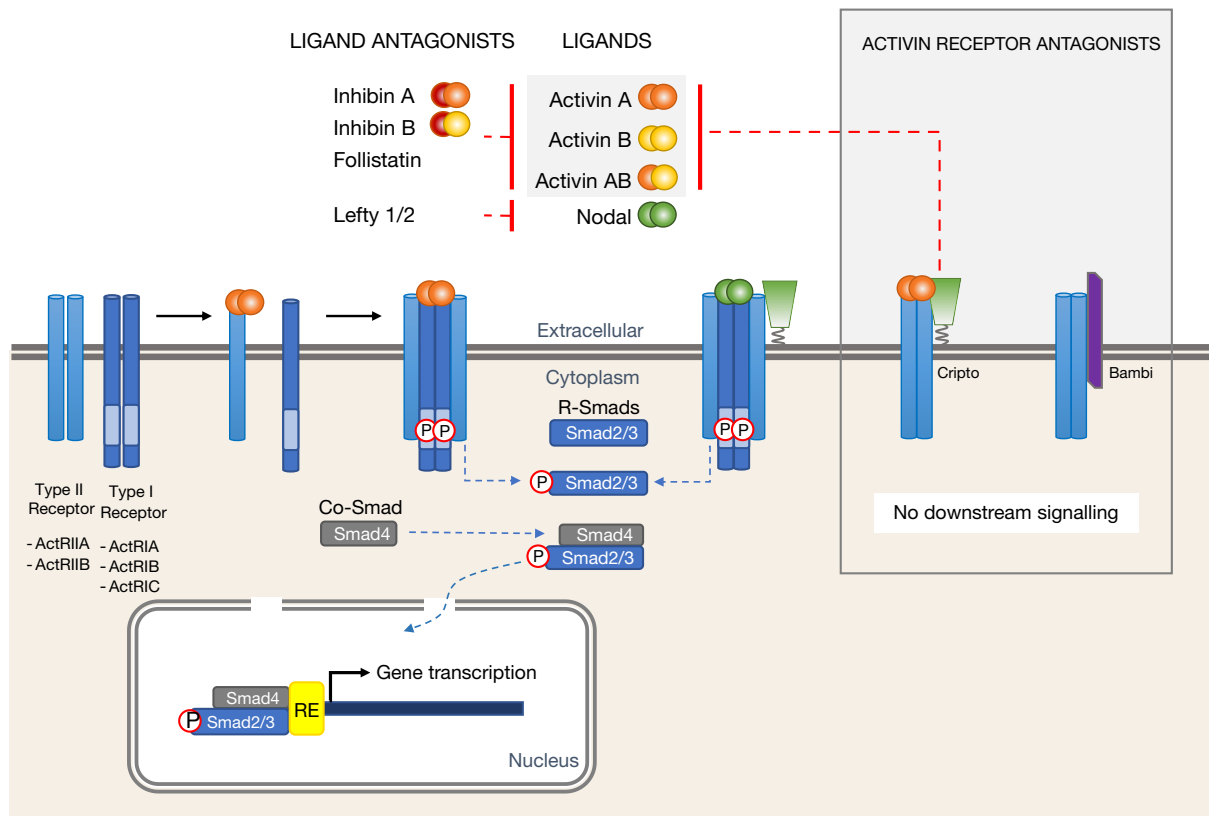

Fig. 1 Activin signaling machinery and inhibitors. Dimeric ligands (activin A, B, and AB) signal by binding to Type II then Type I receptor subunits. The heterotetrameric receptor subunits recruit and phosphorylate Smad2 and 3, which then bind Smad4 and translocate into the nucleus to activate target genes. Inhibitors include soluble and membrane-associated antagonists, as well as intracellular proteins.

ActRIIB (encoded by *ACVR2B*) and also ActRII (also termed ActRIIA, encoded by *ACVR2A*) (Fig. 1). This enables recruitment and activation via phosphorylation of a Type I receptor, typically ALK4 (ActRIIB) for activin A and ALK7 (ActRIC) for activin B.

The activated Type I receptor can recruit and phosphorylate SMAD2 and/or SMAD3 molecules. C-terminal phosphorylation of these regulatory Smad proteins leads two of them to associate with a single SMAD4 molecule. Termed the common SMAD, or co-SMAD, SMAD4 is recruited during signal transduction by nearly all TGF β ligands, while regulatory Smads (R-Smad; includes SMAD1, 2, 3, 5, and 8) and receptor subunit utilization profiles are ligand-specific. Nuclear import of the trimeric Smad complex is mediated by binding to importin proteins; SMAD2 and SMAD3 delivery into the nucleus allows them to bind DNA directly, and to interact with transcriptional cofactors to promote transcription from SMAD binding elements (SBEs) in target gene promoters (reviewed in Hill, 2016). Alternative splicing of SMAD2 transcripts predominantly yields a long isoform that does not bind DNA, while an isoform lacking exon 3 does. SBEs feature direct or inverted repeats of the AGAC consensus sequence near the transcription start site, but specific binding can also be determined by the complement of cell- and developmentally-regulated cofactors such as Forkhead box protein H1 (FOXH1, also known as FAST-1), c-Jun, c-Fos, NANOG, and OCT4 (pluripotency factors) and TAZ, YAP, and TEADs (Hippo pathway transcription factors). Some cofactors have suppressive effects, moderating signaling inputs from TGF β ligands. Posttranslational modification of SMADs via acetylation, poly-ADP-ribosylation and monoubiquitylation can influence their transcriptional activity (Hill, 2016). Thus, the specific cell and tissue context determines the outcomes of activin binding to its receptors.

Common and Distinct Machinery for Signal Transduction by TGF β Superfamily Ligands

Central to activin functions are the complex interactions with other TGF β superfamily ligands through shared and separate signaling pathways. The three prototypical superfamily members, TGF β 1-3, signal through Type I and Type II homodimeric receptors that are not used by other ligands, and TGF β 2 is uniquely reliant on a third nonsignaling receptor, TGFBR3 (also named betaglycan) to signal. Despite activating different receptors, activins and TGF β s both initiate signal transduction by inducing phosphorylation of SMAD2 and SMAD3. Important cell-specific roles for these SMADs have been delineated, for example with SMAD3 in proliferating Sertoli cells (see Section “Activins in Infant and Juvenile Testes”). The bone morphogenetic proteins (BMPs) also share signaling receptors with activin, but their binding triggers recruitment and phosphorylation of SMAD1, 5, and 8.

Although SMAD4 is common to the transduction cascade for each of these signals, target gene activation of is conveyed through unique binding to ligand-specific genomic response elements. For example, Nodal also signals through the same receptors as activin to phosphorylate SMAD2 and 3, however the relative intensity of activin A versus Nodal signaling can direct SMADs to different binding elements. In this manner, the relative abundance of each ligand and intracellular suite of coactivators determines the profile of target gene activation, mediating the diverse array of responses characteristic of this family.

Signaling Inhibitors, Competitors, and Enhancers

Bioactivity of activins and other TGF β superfamily ligands is controlled by a plethora of regulatory molecules with distinct and overlapping roles (Fig. 1). The synthesis of inhibin α and β C subunits within cells producing either activin β A or β B subunits leads to inhibitory dimer formation and decreases production of signaling-active activin. Potent and abundant extracellular, soluble regulators also include follistatin and follistatin-like3 (also termed FSTL3 and follistatin-related protein). The Nodal co-receptor, CRIPTO, impairs activin signaling by blocking its access to receptor subunits. The membrane anchored BAMBI shares structural homology with the Type 1 receptors, blocking downstream signal propagation due to the absence of an active intracellular kinase domain. Intracellular inhibitors of activin signaling include SMAD 7, SKI, and SKIL (previously termed SnoN), with SKIL synthesis induced by TGF β pathway activation. Synthesis profiles for many of these have been mapped during testis development and associate with distinct spermatogenic stages; physiological roles of many have been addressed by examination of mice lacking these genes (Itman et al., 2011).

Activin and Inhibin Synthesis: Links With Functional Roles

Inhibin Subunit Production

The testis is central to the complex and interdependent pathways and cellular sites of synthesis which maintain the activin bioactivity levels required for testis growth and ongoing spermatogenesis. The roles of activin in the seminiferous epithelium that include blood–testis barrier regulation and control of germline differentiation (Sections “[Activins in Infant and Juvenile Testes](#)” and “[Activin Roles in Adult Testes and in the Epididymis](#)”) highlight the importance of balanced and coordinated local inhibin and activin subunit production to fertility.

The inhibin α subunit, encoded by the *INHA* gene, appears to be synthesized solely within Sertoli cells in adults, triggered predominantly in response to FSH stimulation of its receptors. FSH-induced activation of the *INHA* promoter cyclic-AMP (cAMP) response element can be partly enhanced by androgens. In the highly polarized Sertoli cells of adults, both apical and basal secretion of inhibin have been demonstrated in vitro. The central role of circulating inhibin for hypothalamo-pituitary–gonad (HPG) axis regulation is established (Section “[Activin in the Hypothalamic–Pituitary–Gonadal Axis](#)”), though whether inhibin impacts directly on haploid germ cells in the lumen as originally proposed is unverified.

The potential for developmentally regulated control of inhibin synthesis throughout the Sertoli cell lifespan is not fully delineated; the stimulus for upregulation of *INHA* synthesis in fetal Sertoli cells after sex-determination is not understood (Young et al., 2015). In addition to FSH, other signaling moieties have been implicated from in vitro studies to modulate inhibin α subunit production, with results varying with the species and age of the originating animal from which the cells were derived. Factors that influence inhibin secretion in cultured cells include testosterone, estrogen, and epidermal growth factor; culture methods may also influence the outcomes, as culture densities influence Sertoli cell responses to FSH.

Activin Subunit Synthesis

In contrast to inhibin, activin subunit production occurs throughout the body. Activin β A subunit synthesis is stimulated by classic proinflammatory factors, such as those acting through the interleukin-1/Toll-like receptor (IL1/TLR) pathway via Myd88, tumor necrosis factor (TNF), lipopolysaccharide (LPS), reactive oxygen species (ROS), colony stimulating factor 2, IL13, CD40L, TGF β , and interferon γ (IFN γ) (Loveland and Hedger, 2015). This is central to the roles of activin A as a mediator of myeloid lineage cell (monocyte and macrophage) functions. Macrophages and dendritic cells can both produce and be affected by activin A. Both retinoic acid and glucocorticoids can downregulate monocyte activin A synthesis, while T cell production of granulocyte-macrophage colony-stimulating factor (GM-CSF) and IFN γ may increase it (Chen and Ten Dijke, 2016). Activin A is produced by several testicular cell types, including gonocytes and peritubular myoid cells in the developing testis, and in spermatocytes, Leydig cells, mast cells, and macrophages in adults. Activin B subunit synthesis in spermatocytes and spermatids demonstrates the potential for multiple activin isoforms to be functioning within the seminiferous epithelium. Studies of cultured Sertoli cells highlighted differential control of the activin A and B subunits, with inflammatory cytokines inducing activin A but not activin B subunit synthesis. Coculture with pachytene spermatocytes suppressed Sertoli cell inhibin β B-subunit synthesis, highlighting the likelihood of complex, local modulation of activin bioactivity.

An important feature of activin production in adult testes is its controlled release at specific stages of the seminiferous epithelium cycle, linked with functional changes in the blood–testis barrier and spermiation. FSH exposure and intracellular cAMP elevation stimulates, and IL1/TNF inhibits, inhibin α -subunit production in Sertoli cells, and they have the opposite effect on β A-subunit synthesis. This reciprocal regulation underlies the highly stage-specific expression of inhibin B and activin A throughout the cycle,

with a decline in inhibin and an increase in activin A synthesis occurring during elongating spermatid release into the tubule lumen (termed spermiation). Sertoli cells phagocytose the residual germ cell cytoplasm, and inflammatory gene expression is increased in both germ and Sertoli cells. This part of the seminiferous epithelium cycle regulated by activin bioactivity is central to mediating release of spermatozoa in sufficient numbers for male fertility.

Similar to *INHBA*, synthesis of both *INHBA* and *INHBB* transcripts is upregulated in the fetal mouse testis during the week after sex determination (Young et al., 2015). Activin A levels peak as male germline cells in the fetal testis, termed gonocytes or prospermatogonia, transform into spermatogonia to initiate the first spermatogenic wave and form the stem cell population that persists throughout adulthood (Barakat et al., 2008). The important recent studies showing that adequate macrophage numbers within fetal and adult testes are crucial for normal testicular growth and for maintenance of spermatogonial stem cells indicate an as yet unexplored importance of activin A bioactivity for governing immune cell actions within the testis at different stages of development. How changes in activin and inhibin levels are initiated and regulated during testicular development remains to be determined, along with the mechanisms that govern their storage, secretion, and degradation.

Activin in the Hypothalamic–Pituitary–Gonadal Axis

Circulating levels of gonadal-derived activin and inhibin proteins are central to male reproductive function, as these provide reciprocal signals to mediate control of the HPG axis (Fig. 2). Gonadotrophin releasing hormone (GnRH) production within the hypothalamus is affected by several gonadal hormones, including estrogen, testosterone, progesterone, and activin bioactivity levels, with the latter determined locally by activins, inhibins, and follistatin. Pulsatile GnRH release acts on the pituitary gland to drive synthesis of FSH and leutinizing hormone (LH), which are comprised of a common α subunit and a distinct β subunit. Activin B signaling stimulates FSH β subunit synthesis in pituitary gonadotrophs and promotes FSH production; this is directly blocked by inhibin, which prevents receptor binding and activation. Activin A promotes LH β subunit synthesis, and is antagonized by testosterone. This highlights the physiological importance of the differing receptor engagement and distinct signaling pathway outcomes engaged by each activin subunit. Circulating FSH levels are directly linked in juveniles to testis growth and in adults to sperm production through its actions on Sertoli cells, while maintenance of LH levels is linked to Leydig cell development and function, including directly influencing testosterone production.

Dynamic and Developmentally Regulated Actions Within the Testis

Activins in the Fetal Testis

Sertoli cells form the essential niche for male germline development. They provide essential cues for the sexually indifferent primordial germ cells arriving at the gonadal ridge to enter the male differentiation pathway by mouse embryonic day 11.5 (E11.5), evoking changes in other somatic cells which result in formation of seminiferous cords within an appropriate milieu of interstitial

Fig. 2 Reciprocal control of the hypothalamic–pituitary–gonadal (HPG) axis by the endocrine actions of gonadal-derived activin and inhibin proteins. The hypothalamus produces gonadotrophin releasing hormone (GnRH), which in turn drives FSH synthesis in the pituitary. FSH production is facilitated by activin signaling in pituitary gonadotrophs to stimulate FSH β subunit synthesis. Activin signaling is directly blocked by inhibin, which prevents receptor binding and activation. Circulating FSH levels are directly linked in juveniles to testis growth and in adults to sperm production.

cells. Gonocytes proliferate for approximately 2 days, and by E13.5 become quiescent until shortly after birth in rodents. Crucial epigenetic reprogramming of the male germline occurs during this week of fetal life, featuring essential genome-wide demethylation and remethylation to prepare the naïve genome of the earliest sperm precursors (reviewed in [Young et al., 2015](#)). The extent of Sertoli cell proliferation in the fetus and neonate prior to puberty is a strong determinant of adult sperm output, because individual adult Sertoli cells can support simultaneous maturation of a finite number of germ cells.

Inhibin α , β A, and β B subunit mRNAs are elevated in male, but not female, gonads after sex determination. In contrast, upregulation of the *FST* transcript, encoding follistatin, in ovaries suppresses vasculature formation. Analysis of *Inhba* $-/-$ mice, lacking the activin A subunit, provided evidence that activin A drives fetal Sertoli cell multiplication. In these mice, initial events of testicular formation are normal as germ cells become enveloped within Sertoli cell cords. However, Sertoli cell proliferation and the cyclin D2 transcript (*Ccnd2*) were reduced in knockouts by E15.5, and Sertoli cells number at birth in was significantly lower. A subtle but inverse effect on germ cells was detected slightly earlier in *Inhba* $-/-$ testes: the *Cdkn1a* transcript, encoding the p21^{kip1} cell cycle inhibitor in gonocytes, was lower in heterozygous and knockout testes only at E13.5, and increased germ cell numbers were identified using stereological methods. TGF β has a similar inhibitory effect of on fetal gonocyte multiplication in vivo ([Mendis et al., 2011](#)). Because *Inhba* $-/-$ mice die at birth, this model cannot be used to examine activin A depletion in adults. However, selective *Inhba* removal from Leydig cells or of *Smad4* from Sertoli cells (rendering them nonresponsive to activin A and to other TGF β ligands) both yielded shorter, truncated testis cords ([Archambeault and Yao, 2010](#)). These results, extended by additional analyses of fetal testis development, demonstrated an important role for locally produced activin A, particularly from Leydig cells, in the crosstalk between somatic cells that drives the expansion and likely coiling of the testis cords late in fetal development, which ultimately facilitates normal testis development and function.

Immediately after sex determination and prior to the marked elevation of inhibin and activin transcripts, Nodal and its signaling regulators, Lefty1 and Cripto, are upregulated in germ cells. This can sustain germ cell pluripotency and may prevent the inappropriate germline entry into meiosis that occurs normally in female fetal gonads. Thus, a complex interplay of signals between several TGF β superfamily ligands contributes to overall testis growth, with each serving cell-specific roles and several likely to interact with other signaling pathways.

Activins in Infant and Juvenile Testes

Sertoli cell proliferation is maximal around birth in rodents and continues around 12 days in mouse and 16 days in rats. Loosely analogous to human puberty, at this time Sertoli cells transform into nonproliferative cells joined by complex junctions, forming the highly polarized seminiferous epithelium required to support meiotic and haploid phases of spermatogenesis.

The male germ cells present at birth in rodents are quiescent gonocytes, centrally positioned within seminiferous cords formed by proliferating Sertoli cells. The cords are surrounded by a dynamic extracellular matrix and proliferating peritubular cells within a loose interstitium of proliferating Leydig cells, fibroblasts, sparse immune cells, and lymphatic, and blood vessels. Within 1 day after birth in mice (3 days in rats), gonocytes resume mitosis and move radially to contact the cord basement membrane, becoming spermatogonia. At this initiation of spermatogenesis, approximately 50% of spermatogonia begin differentiation immediately to form the first sperm over the following 5–6 weeks; the remainder become the spermatogonial stem cells which self-renew to enable production of sperm throughout adult life. Cells that fail in this gonocyte-to-spermatonium transformation are removed by apoptosis. Disruptions to this may underpin emergence and/or maintenance of the “germ cell neoplasia in situ cells” (GCNIS cells) that precede emergence of testicular tumors in young men (Section “[Testis Cancer and Potential Links With Endocrine Disrupting Chemicals](#)”).

Fetal gonocytes synthesize the activin β A subunit transcript and protein; the transcript is absent at birth but the protein persists. The β A protein is absent from nascent spermatogonia, and the activin antagonists, Follistatin and Bambi are produced ([Fig. 1](#); reviewed in [Young et al., 2015](#)). Activin A sources in the juvenile testis include Leydig and peritubular cells and spermatocytes.

Tight regulation of activin signaling as spermatogonial differentiation commences is potentially linked with the effects of Nodal and bone morphogenetic protein BMP8A to promote spermatogonial proliferation, and the support of spermatogonial stem cell multiplication by the noncanonical family member, Glial cell-derived neurotrophic factor (GDNF). Additionally, BMP4, BMP8A, and BMP8B can also support spermatogonial differentiation. Because all signaling machinery elements are shared by the multiple TGF β superfamily ligands present, the local, tight regulation of their production and activity at the onset of spermatogenesis and during juvenile testis development is important to adult fertility.

Studies of mice lacking activin and inhibin subunits, most notably those generated by Matzuk and colleagues (reviewed in [Namwanje and Brown, 2016](#)), demonstrated effects of activin bioactivity on testes and many other organs. Some aspects of their chronic dysregulation on male reproduction are relatively subtle and may reflect biological redundancies and/or a moderating role for activin in mediating growth and homeostasis.

Inhibin α subunit absence (*Inha* $-/-$ mouse; [Matzuk et al., 1992](#)) does not grossly affect initiation of spermatogenesis, however the resulting high activin levels drive Sertoli cell proliferation past day 12. Sertoli cell-like tumors emerge at 4 weeks, with spermatogenesis progressively lost and adrenal tumors forming later. This identified inhibin as a tumor-suppressor that suppresses activin and allows p27^{kip1} inhibition of cyclinD2/E1 and Ck4/2 cell cycle complexes in Sertoli cells. Deletion of *Smad3* prevents this phenotype, while *Smad2* deletion has no effect; granulosa cell tumor formation in *Inha* $-/-$ females is reduced by *Smad2* deletion. In *Smad3* $-/-$ mice with normal activin/inhibin levels, Sertoli cell maturation is delayed, while Sertoli cells mature earlier in *Smad3* $+/-$ mice and support earlier germ cell maturation in juveniles. Such strict dependency on *Smad3* for Sertoli cell

proliferation coincides with a barrier to phosphorylated Smad2 nuclear entry that is absent from postmitotic cells. Distinct activin gene targets are identified for proliferating versus postmitotic Sertoli cells, linked to differences in activin exposures (Itman et al., 2009). The distinct expression profiles of individual Smads during Sertoli and germ cell development indicate they perform specific roles related to the many different TGF β signaling moieties for which they transduce and regulate gene transcription.

Fertility is unaffected in mice lacking the β B subunit gene. Because *Inhba* $-/-$ mice die at birth, to study activin A postnatal roles, the *Inhba*^{BK/BK} mouse with reduced activin bioactivity (~ 10 -fold lower at sites of β A activity) was generated by replacing the activin β A mature coding sequence with that of β B. These mice usually reach adulthood and can reproduce, but first sperm production occurs 9 days late. Newborn and 7 day old mouse testes contain more germ and Leydig cells compared to wild type littermates, and 7 day testes have fewer Sertoli cells. Similar to *Inhba* $-/-$ testes, the Sertoli to germ cell ratio is lower, indicative of reduced Sertoli cell proliferation in activin A insufficiency conditions. Germ cell differentiation markers do not follow normal patterns in juvenile *Inhba*^{BK/BK} mice, highlighting somatic and germ cell interdependency.

Other hormones interact with activin in juveniles. Sertoli cell proliferation is greatly enhanced by FSH in the second week of life, as shown in culture experiments and through neutralization of FSH bioactivity in *Inha* $-/-$ mice; in the latter, the outcome on Sertoli cell tumor development supports the understanding that this is developmentally-regulated. Activin A also regulates androgen receptor and androgen target gene production, and it modulates FSH-induced aromatase activity; *Inha* $-/-$ mice lacking a functional androgen receptor exhibit a slightly milder tumor phenotype. Thus, activin bioactivity is tightly regulated for appropriate testicular development. It directly influences Sertoli and germ cell maturation to determine the timing of pubertal onset through multiple mechanisms.

Activin Roles in Adult Testes and in the Epididymis

The blood–testis barrier (BTB) that forms from specialized junctions between adjacent Sertoli cells in the seminiferous epithelium is critical for adult fertility, restricting contact between postmitotic germ cells and the immune system and preventing rejection of spermatogenic cells that form after immune tolerance establishment. This complex structure changes throughout the seminiferous epithelium cycle, allowing adluminal movement of differentiated spermatogonia entering meiosis. Activin, along with TGF β , contributes to the cyclical loosening and reformation of this barrier.

The chronic absence of activins or inhibins, or reduction in their activity, has sequelae for male fertility which belie the complex integration of developmental cues affecting male fertility. Such outcomes are subtle and some differ with development. For example, while the testis, epididymis and vas deferens in 25 day *Inha* $-/-$ mice appear normal, the progressive loss of spermatogenic capacity at 8 weeks is accompanied by marked regression of Leydig and excurrent duct epithelial cells, and by a state of androgen insufficiency. *Inba* $+/-$ mice exhibit phenotypic variation throughout development, with adjacent tubules exhibiting advanced and depleted spermatogenesis at 16 days of age that is resolved by 4 weeks. By 8 weeks, *Inba* $+/-$ testes are larger and produce more sperm than littermates, and at 26 weeks they display reduced spermatogenesis, proliferating Sertoli cells and evidence of reduced Leydig cell steroidogenic capacity. As described in Section “Activins in Infant and Juvenile Testes,” substitution of the activin β A subunit with β B in the *Inhba*^{BK/BK} mouse does not result in structural abnormalities of either testis of epididymis at 8 weeks, nor does the absence of one *Inhba* allele impact grossly on fertility. These results indicate normal testis development and function can occur within a range of activin bioactivities, while close scrutiny identifies developmental windows and specific cell types which are affected by altered activin bioactivity.

Activin A in culture can support proliferation of rodent stem and progenitor Leydig cells and prevent their differentiation. A gradient of activin production along the epididymis, from high in the caput to low in the cauda, where follistatin levels increase, affect immune cell functions, duct coiling and no doubt other processes along this tract and into the vas deferens that are yet to be revealed. Importantly, each of these functions occurs within the context of signaling by other TGF β superfamily members and different signaling pathways, so that activin does not solely determine functional outcomes.

Clinical Applications and Links to Testicular Pathologies Affecting Male Reproductive Health

Activins and Inhibins as Biomarkers and Therapeutic Targets

Circulating inhibin B is an established measure of spermatogenesis and Sertoli cell functionality, correlating with testicular size and sperm count. Inhibin B levels may also predict adult fertility in juveniles with conditions affecting testicular function. Inhibin B is made in Sertoli cells and possibly spermatocytes, while both Sertoli and Leydig cells have been identified as producing the inhibin α subunit proregion peptide, pro- α C. The elevation of serum FSH levels in infertile men in which spermatogenesis is disrupted may arise from changes in Sertoli or Leydig cell function or reflect differing testicular cellularity. In adult men, inhibin B and FSH levels in serum are inversely correlated, and inhibin A is not detectable. Conditions which suppress spermatogenesis, such as GnRH or steroid treatment, chemotherapy or irradiation, can have mild to significant impacts on inhibin levels that reflect testicular function.

Production of activin within the testis does not appear to contribute significantly to circulating levels, including during systemic inflammation, when activin is elevated in serum. Seminal glands and epididymides are both potential sources of activin A found in seminal plasma, while the origin of activin B in human seminal fluid is unknown.

Expanding knowledge of immunomodulatory roles for activins (Chen and Ten Dijke, 2016) has led to investigations of its potential as a therapeutic target in conditions of testicular inflammation. In a model of autoimmune epididymo-orchitis, in which

mice are immunized with testis extracts and exhibit testicular immune cell infiltrations, testicular fibrosis and germ cell loss that mimic human disease, the peak of elevated *Inhba* expression was concurrent with active disease. Agents such as follistatin, soluble activin receptors and modified activin prodomains are under investigation as compounds that may mitigate the chronic effects of acute and ongoing inflammation to reduce damage to the testis and epididymis, and thereby preserve fertility.

Testis Cancer and Potential Links With Endocrine Disrupting Chemicals

The rate of testicular cancer continues to increase world-wide, associated with a spectrum of phenotypes referred to as the testicular dysgenesis syndrome, including hypospadias and cryptorchidism; each may impair male fertility and have potential comorbidities. Both genetic and environmental mechanisms may support GCNIS cell emergence and progression into seminomas or nonseminomas in young men. Disrupted androgen activities, through exposure to endocrine disrupting compounds, represent a likely component, potentially linked with altered TGF β superfamily activity.

Activin, Nodal and BMP signaling components have each been implicated in testicular germ cell tumors. The upregulation in testicular tumors of activin inhibitors, inhibin α , betaglycan, and Cripto, and of its competitor, Nodal, indicates activin blockade may be required to sustain these tumors. Circumstances leading to disruption of either or both BMP and activin signaling may enhance the opportunity for Nodal to sustain pluripotent germ cells into adulthood, where the dynamic milieu of the postpubertal seminiferous epithelium can support their expansion as seminomas and inappropriate differentiation as nonseminomas.

Because activin and inhibin functions affect all stages of testis development and are intimately linked with hormone production and function, the potential impact of endocrine disruptors on this pathway has been investigated. Exposure of mice to di-*n*-butyl phthalate (DBP) daily from day 4 to 14 exhibited reduced Sertoli cell multiplication and anogenital distance (indicating reduced androgen bioactivity), while increasing inhibin levels. Integration of knowledge about activin signaling, inhibin functions and endocrine disruptor actions may provide important information about how environmental signals affect reproductive health.

Introduction

Testicular Leydig cells are the primary source of androgens, which are indispensable for the development of the male reproductive system. Androgens synthesized by the interstitial Leydig cells include testosterone, 5 α -dihydrotestosterone, androstenedione, androstanediol, and androsterone (Payne and Hales, 2004; Teerds and Huhtaniemi, 2015). Among these, testosterone is the most prevalent male sex androgen. Testosterone induces masculinization before birth, drives the establishment of male secondary sexual characteristics after birth and supports spermatogenesis throughout life (Payne and Hardy, 2007).

There are two classes of enzymes involved in androgen biosynthesis: the cytochrome P450 heme-containing proteins and the hydroxysteroid dehydrogenases. These enzymes are located in mitochondria and smooth endoplasmic reticulum (SER), respectively, and they catalyze the conversion of cholesterol to androgens. Notably, the prevalent androgens produced by Leydig cells at each developmental stage are different due to the developmental, stage-specific expression of steroidogenic enzymes (Ye et al., 2017). Given that testosterone is considered to be the most important androgen for masculinization and spermatogenesis, we will mainly discuss testosterone biosynthesis in this article.

Source of Cholesterol

In Leydig cells, cholesterol is synthesized de novo from acetate. Besides de novo synthesis, plasma lipoproteins bring cholesterol to Leydig cells (Hu et al., 2010). The de novo pathway is preferably used in the rat and lipoproteins in humans (Payne and Hardy, 2007). Cholesterol can be stored in the form of cholesterol esters in lipid droplets or come from various membranes e.g. plasma membrane.

Acetate

Under normal physiological conditions, Leydig cells preferentially synthesize cholesterol de novo from acetate (Fig. 1). Among numerous enzymes required for the conversion of acetate to cholesterol, 3-hydroxy-3-methylglutaryl (HMG)-CoA-reductase (HMGCR) located in the SER is the rate-limiting enzyme that catalyzes the condensation of acetyl-CoA into mevalonate. De novo synthesis of cholesterol is also under the control of pituitary luteinizing hormone (LH). The newly formed cholesterol will be transferred from the endoplasmic reticulum to the plasma membrane. Excess cholesterol is converted to cholesterol esters by acetyl-CoA acetyltransferase (ACAT1) and packed into lipid droplets.

Plasma Lipoprotein and Intracellular Cholesterol Esters

Newly synthesized cholesterol esters are the source of cholesterol for androgen synthesis in response to trophic hormone stimulation. Depending upon conditions, however (e.g., LH-induced desensitization of the steroidogenic response), Leydig cells may utilize plasma lipoprotein as the source for cholesterol synthesis (Fig. 1). In this scenario, cholesterol may come either from plasma low-density lipoprotein (LDL) or high-density lipoprotein (HDL). Cholesterol esters released from LDL are delivered to the plasma membrane or to lipid droplets and mitochondria for androgen synthesis. Cholesterol esters from HDL are hydrolyzed and the released free cholesterol is used for androgen synthesis.

Plasma Membrane

In mammalian cells, free cholesterol is abundant in the plasma membrane (Maxfield and Wustner, 2002). The origin of this cholesterol could be from either de novo synthesis or lipoprotein import and processing. Hormone-treatment of Leydig cells induces rapid mobilization of free cholesterol from the inner leaflet of the plasma membrane to mitochondria for steroid synthesis (Freeman, 1989; Venugopal et al., 2016). This cholesterol constitutes the pool of free cholesterol used for steroidogenesis in response to LH stimulation until de-esterification of stored cholesterol provides large amounts to sustain steroidogenesis.

Biosynthesis of Androgens From Cholesterol

Mobilization of Cellular Cholesterol

As noted above, cholesterol is released from the plasma membrane and then lipid droplets upon trophic stimulation by LH or human chorionic gonadotropin (hCG). LH/hCG binds to a G protein-coupled receptor that activates the adenylate cyclase leading

Fig. 1 Molecular and cellular events involved in testosterone biosynthesis in Leydig cells. In Leydig cells, androgens are derived from cholesterol. This figure depicts testosterone synthesis in Leydig cells. Cholesterol is either derived by de novo synthesis or from low-density lipoprotein (LDL) or high-density lipoprotein (HDL). Following this, cholesterol is delivered to mitochondria for the first step of testosterone biosynthesis. At the inner mitochondrial membrane (IMM), cholesterol is catalyzed to pregnenolone by CYP11A1. Pregnenolone is translocated from mitochondria to smooth endoplasmic reticulum, at which it is further processed to testosterone and other androgens. Then testosterone is secreted by Leydig cells. FC, free cholesterol; CE, cholesterol ester; SR-B1, scavenger receptor class B, type I.

to cyclic adenosine 3',5'-monophosphate (cAMP) production. cAMP-dependent protein kinase then is activated to initiate a series of events that includes the mobilization of free cholesterol in the plasma membrane and phosphorylation of neutral cholesteryl ester hydrolase (nCEH), leading to the mobilization of cholesterol esters.

Translocation of Cholesterol in Mitochondria

Steroidogenesis begins with the transfer of free cholesterol from the plasma membrane and intracellular stores into mitochondria—the rate-limiting step in androgen biosynthesis. This initial rapid response to LH, and its second messenger cAMP, is mediated

by hormone-sensitive protein synthesis, protein–protein interactions, and organelle communications. Chronic stimulation by LH is required for optimal expression of steroidogenic enzymes leading to sustainable steroid formation.

The first catalytic reaction in androgen biosynthesis occurs in mitochondria. Before this reaction, cholesterol must be translocated from its various locations in the cell to the outer mitochondrial membrane (OMM). This may occur through either a vesicular or non-vesicular transport pathway (Fig. 1). An important mechanism of vesicular transport is the delivery of cholesterol through protein–protein interactions. There is evidence that there is increased association of mitochondria with the endoplasmic reticulum in Leydig cells in response to hormone treatment mediated via AAA+ ATPase domain 3 (ATAD3) protein (Issop et al., 2015). It is also possible that the soluble *N*-ethylmaleimide-sensitive factor attachment receptor (SNARE) complexes facilitate the delivery of cholesterol by promoting functional protein–protein interactions between lipid droplets and mitochondria (Lin et al., 2016). Indeed, there is strong interorganelle interactions that facilitate free cholesterol exchange in response to LH in Leydig cells (Issop et al., 2013). Cholesterol also can be delivered through a non-vesicular transport pathway, mediated by high-affinity cholesterol-binding proteins including steroidogenic acute regulatory protein (STAR). In particular, STARD4 has high affinity with free cholesterol and is involved in cholesterol transport (Mesmin et al., 2011).

Cholesterol targeting into mitochondria is mediated by the formation of a mitochondrial scaffold, the transduceosome, created by protein–protein interactions of cytosolic and OMM proteins (Rone et al., 2009). After cholesterol is translocated to the OMM, it will be delivered to the inner mitochondrial membrane (IMM), where it is converted to pregnenolone by CYP11A1 (Fig. 1). Cholesterol is imported and metabolized by the 800-kDa bioactive metabolon, composed of the OMM/IMM translocator protein (TSPO), voltage-dependent anion channel (VDAC), ATAD3, and CYP11A1 (Rone et al., 2012). The rapid induction of STAR formation by LH and its subsequent targeting and insertion into OMM leads to accelerated cholesterol delivery to CYP11A1 (Rone et al., 2012; Papadopoulos and Miller, 2012).

Biosynthesis of Testosterone From Cholesterol

The process of testosterone biosynthesis from cholesterol involves four enzymes: cytochrome P450 family 11 subfamily A1 (CYP11A1), 3 β -hydroxysteroid dehydrogenase/ $\Delta^5 \rightarrow \Delta^4$ isomerase (3 β -HSD), CYP17A1, and 17 β -HSD3 (Miller and Auchus, 2011; Payne and Hales, 2004). CYP11A1 is located in mitochondria, 3 β -HSD is present in mitochondria but predominantly found in SER, and CYP17A1 and 17 β -HSD3 are found only in SER (Figs. 1 and 2).

CYP11A1

CYP11A1, which is generically termed cytochrome P450 (P450_{scc}), is a 56-kDa enzyme located in the IMM (Fig. 1). It catalyzes the conversion of cholesterol to pregnenolone (Fig. 2). This conversion includes three sequential oxidation reactions: hydroxylation of cholesterol at C22, hydroxylation of 22(R)-hydroxycholesterol at C20, and cleavage of the C20–22 bond of 20(R), 22(R)-dihydroxycholesterol to yield pregnenolone and isocaproaldehyde. All three reactions are catalyzed in the same site of CYP11A1. The mitochondrial environment is required for the catalytic activity of CYP11A1 since CYP11A1 is lacking mitochondrial leader and when targeted to the ER is inactive. During the conversion, CYP11A1, a monooxygenase, catalyzes oxidation by utilizing electrons from reduced nicotinamide adenine dinucleotide phosphate (NAPDH). A mitochondrial electron transport system consisting of ferredoxin reductase (FdR) and ferredoxin (FdX) facilitates the electron transport between CYP11A1 and NAPDH.

CYP11A1 determines the biosynthetic capacity of Leydig cells. The amount of CYP11A protein is primarily decided by transcription of the *CYP11A* gene, which can be regulated in a hormonally responsive fashion. The transcription of the *CYP11A* gene is induced by both cAMP and cAMP-dependent protein kinase. Upon LH stimulation, the activation of cAMP is necessary for the expression of involved enzymes in androgen synthesis. Steroidogenic factor 1 (SF1) also is essential for androgen synthesis, involved in the regulation of the expression of CYP11A and other steroidogenic enzymes.

3 β -HSD

Pregnenolone diffuses passively from the mitochondria to SER for further processing. Although 3 β -HSD is found in mitochondria, it is abundant in SER (Fig. 1) in proximity to CYP17A1 and 17 β -HSD3 so that each intermediate of testosterone synthesis can move directly to the next enzyme. Depending upon the species, Leydig cells use either the Δ^4 or Δ^5 pathway to produce testosterone (Fig. 2). Rodent Leydig cells preferentially follow the Δ^4 pathway while human and rabbit Leydig cells follow the Δ^5 pathway. In the Δ^4 pathway, pregnenolone is converted to Δ^4 steroids by 3 β -HSD. 3 β -HSD is a 42-kDa enzyme that converts pregnenolone to progesterone (Fig. 2). Additionally, it can also convert 17 α -hydroxypregnenolone to 17 α -hydroxyprogesterone (17OHP), dehydroepiandrosterone (DHEA) to androstenedione, and androstenediol to testosterone. Two chemical transformations are catalyzed by 3 β -HSD to stimulate these conversions (Fig. 2). First, the 3 β -hydroxyl group of the substrate is oxidized to the ketone group, when NAD⁺ is converted to NADH. Next, NADH activates the second activity of 3 β -HSD, the $\Delta^5 \rightarrow \Delta^4$ isomerase activity, i.e. catalyzing the isomerization of the double bond from carbon 5 and 6 to carbon 4 and 5, to yield Δ^4 steroid.

CYP17A1

Human and rabbit Leydig cells synthesize testosterone via the Δ^4 pathway, in which the first reaction is catalyzed by CYP17A1. CYP17A1 is a 57-kDa enzyme that expresses both 17 α -hydroxylase and 17, 20-lyase activities. In the Δ^5 pathway, CYP17A1 converts pregnenolone to 17 α -hydroxypregnenolone (Fig. 2). Then it converts 17 α -hydroxypregnenolone to DHEA by its 17, 20-lyase activity (Fig. 2). The presence of cytochrome *b*₅ increases the rate of lyase reaction more than 10-fold. In addition to the two-step conversion

Fig. 2 Androgen biosynthetic and metabolic pathways in Leydig cells. (Top) In adult Leydig cells (ALCs), androgens are synthesized via the classical pathway. The major steps involved in the classical pathway include conversion of cholesterol to pregnenolone and synthesis of testosterone from pregnenolone by following two species-dependent pathways (Δ^4 and Δ^5). (Bottom left) Testosterone is further metabolized to dihydrotestosterone (DHT), 5α -androstane- 3α , 17β -diol and estradiol. In fetal Leydig cells (FLCs), using the backdoor pathway. The critical enzyme employed by the backdoor pathway is 3α -reductase, which converts 5α -androstane- 3α , 17β -diol to DHT. All the enzymes, co-enzymes, electron transport systems and direction of reactions are shown. Androgens are emphasized by larger structural images. The developmental stages during which key enzymes are expressed are included in parentheses. “+” and “-” represent significant and negligible expression levels of enzymes, respectively.

of pregnenolone to DHEA, CYP17A1 can also catalyze the transformation of progesterone to 17OHP. However, under normal conditions, 17OHP is not a critical precursor for androgen synthesis; the conversion of 17OHP to androstenedione catalyzed by CYP17A1 is 50-fold less efficient than the conversion of 17 α -hydroxypregnenolone to DHEA. The reaction catalyzed by CYP17A1 also requires the microsomal electron transport system termed flavoprotein P450 oxidoreductase (POR). POR is a single membrane-bound flavoprotein that receives two electrons from NADPH and delivers them at once to CYP17A1. In human cells, the interaction between POR and CYP17A1 is facilitated by cytochrome *b*₅ and the serine phosphorylation of CYP17A1. As the sole electron transfer system serving for all microsomal P450s, POR also delivers electrons to CYP19A1 for metabolism of androgens.

17 β -HSD3

17 β -HSD3 is a 34.5-kDa enzyme specifically expressed in the testis. It can catalyze DHEA transformation to androstenediol, and androstenedione to testosterone (Fig. 2). Androstenediol derived from DHEA may contribute to testosterone biosynthesis in Leydig cells.

Other Androgens and Estrogens in Leydig Cells

As noted above, in addition to testosterone, Leydig cells synthesize androgens that are intermediate products of testosterone biosynthesis, including DHEA, androstenediol and androstenedione (Fig. 2). Leydig cells also can metabolize androgens into dihydrotestosterone (DHT) and estrogens (Fig. 2).

DHT

DHT is a potent androgen for male sexual differentiation. It is derived from testosterone by a 30-kDa microsomal enzyme, 5 α -reductase. In the fetus, DHT and testosterone induce genital tubercle transformation into male external genitalia. In humans, two isoforms of 5 α -reductase have been identified. Type 1 5 α -reductase potentially contributes to pubertal virilization, as proven by the consequences of classic 5 α -reductase deficiency. Type 2 5 α -reductase, the more prevalent isoform in Leydig cells, is responsible for directing male sexual differentiation. Beyond converting testosterone to DHT, 5 α -reductase, especially the type I isoform, can also metabolize progesterone, 17OHP and related C₂₁ steroids. Moreover, type I isoform expressed in immature mouse Leydig cells participates in androstenediol synthesis via two distinct pathways (Fig. 2).

Estradiol and estrone

In addition to androgens, Leydig cells can also produce estrogens. 17 β -Estradiol derived from testosterone, is the main estrogen formed in Leydig cells. A microsomal enzyme, CYP19A1 (58-kDa), generically termed P450arom, catalyzes the aromatization of testosterone to estradiol. CYP19A1 aromatase also catalyzes the conversion of androstenedione to estrone (Fig. 2). In the male, androgen-derived estrogens contribute to numerous physiological processes, including skeletal maturation.

Developmental-Specific Expression of Enzymes

There are two distinct populations of Leydig cells identified in different stages of male sexual development. Fetal Leydig cells (FLCs) appear at the fetal stage, and a second population, the adult Leydig cells (ALCs), develop from stem cells after birth. The differentiation of ALCs can be divided into four stages: stem Leydig cells (SLCs), progenitor Leydig cells (PLCs), immature Leydig cells (ILCs), and mature adult Leydig cells (mature ALCs). The androgens formed at the various stages of Leydig cell development vary due to the differential expression of steroidogenic enzymes (Fig. 2) (Kotula-Balak et al., 2012; Ye et al., 2017).

FLCs express CYP11A1, 3 β -HSD, CYP17A1, 5 α -reductase, and 3 α -HSD. These enzymes continually increase during the fetal stage. The expression of 17 β -HSD3 is controversial and likely species-specific. In the mouse no 17 β -HSD3 has been detected in FLC; the enzyme is found in the tubular cells of the testis, indicating a possible cooperation between different testicular cells to produce androgens. However, the enzyme is present in rat FLC. At fetal day 15.5, the testis begins to produce testosterone. Its production gradually increases. DHT and androstenedione also are synthesized by FLCs. DHT is essential for the development of the external male genitalia. In FLCs, DHT is derived from progesterone by following the “backdoor” pathway (Fig. 2). Enzymes catalyzing this metabolic pathway include 5 α -reductase, 3 α -reductase, 17 β -HSD3 and 17 β -HSD6. The key enzyme of the “backdoor pathway,” 3 α -reductase, converts 5 α -androstane-3 α , 17 β -diol to DHT.

After the first postnatal week, testosterone declines due to reduced numbers of FLCs and their reduced steroidogenic activities. The level of testosterone is elevated again when ALCs start developing. In rats, ALC differentiation begins around postnatal day 14 and finishes around postnatal day 60. SLCs express no steroidogenic enzymes whereas PLCs express CYP11A1, 3 β -HSD, and CYP17A1 and therefore synthesize androstenedione. PLCs also express androgen-metabolizing enzymes, including 5 α -reductase and 3 α -HSD. These enzymes can metabolize androstenedione into androsterone, which is the main product of PLCs. When PLCs further differentiate into ILCs, CYP11A1, 3 β -HSD, and CYP17A1 are concomitantly increased. The appearance of 17 β -HSD3 enables ILCs to synthesize testosterone. However, due to the continuous presence of 5 α -reductase and 3 α -HSD, testosterone will be metabolized, leading to a high production of 5 α -androstane-3 α , 17 β -diol in ILCs. When ALCs become mature, testosterone production rises significantly as a consequence of increased numbers of LH receptors and thus elevated responsiveness to LH. At the same time, decline of 5 α -reductase activity also contributes to the accumulation of testosterone in mature ALCs. The

large quantity of testosterone secreted by mature ALCs is required for the initiation and the maintenance of spermatogenesis as well as the establishment of secondary sex characteristics in puberty and through adulthood.

Enzymes of Androgen Biosynthesis in Pathological Conditions

Every step of testosterone biosynthesis and the conversion of testosterone to DHT can be disturbed, leading to changes in androgen production and androgen balance. Disruption of androgen synthesis results in disorders of male sexual development (Miller, 2005; Miller and Auchus, 2011).

For example, STAR (STAR1) is a key protein regulating the transport of cholesterol into mitochondria. Mutations of the *STAR1* gene result in a severe genetic disorder of steroidogenesis called lipoid congenital adrenal hyperplasia (CAH). The loss of STAR in CAH leads to over 80% decline of steroids. The affected 46, XY fetuses CAH cannot undergo normal virilization and thus are born with female external genitalia. In patients with a less severe form of lipoid CAH, patients have 20%–25% of normal STAR activity. They have normal external male genitalia but mild hypergonadotropic hypogonadism. The patients with a *CYP11A1* mutation cannot be clinically and hormonally distinguished from those with lipoid CAH.

Mutations of 3 β -HSD1 have not been reported; such mutations would prohibit placental progesterone biosynthesis, leading to a spontaneous first-trimester abortion. The mutations of the *HSD3B2* gene cause 3 β -HSD2 deficiency and consequent decrease of testosterone production. The severely mutated form of 3 β -HSD2 results in lipoid CAH. In patients with this mutation, the level of Δ^5 steroids increases significantly while that of Δ^4 steroids increases slightly, leading to a high ratio of Δ^5 to Δ^4 steroids. Patients with the 17 β -HSD3 deficiency or 5 α -reductase 2 deficiency share the same clinical characteristics as those deficient for 3 β -HSD2; i.e. undermasculinization with hypoplastic-to-normal male internal genitalia, female external genitalia, and loss of the prostate. Additionally, 5 α -reductase 2 deficiencies may be associated with the male pattern baldness. Complete CYP17A1 deficiency includes the absence of both 17 α -hydroxylase and 17,20-lyase activities that inhibit the production of gonadal sex steroids. As a consequence, the affected 46, XY males present with the absence or abnormalities of male external genitalia. Selective deficiency of 17 α -hydroxylase and 17,20-lyase activities has also been identified.

Differences of Androgen Biosynthesis in Human and Rodent Leydig Cells

To date, most knowledge of androgen biosynthesis in Leydig cells has come from studies of rodent models, including steps of androgen synthesis and enzymes involved in this process. In contrast, we understand much less about androgen biosynthesis in humans in part because of the difficulty in obtaining samples. It remains unclear whether the factors identified in rodent Leydig cells play the same roles in human Leydig cells, and/or whether there are novel pathways in human Leydig cells that are involved in producing androgens. However, without doubt, differences of androgen biosynthesis between human and rodent Leydig cells do exist (Teerds and Huhtaniemi, 2015).

In contrast to rodents, three distinct populations of human Leydig cells, FLCs, neonatal Leydig cells (NLCs), and ALCs have been identified during male sexual development. NLCs appear between birth and the 6 months thereafter, concomitant with a unique peak of testosterone production in the human. This testosterone surge is thought to contribute to imprinting of many cell types of androgen-dependent organs. In rodents, no NLCs have been reported. There also are species-dependent differences in both the cholesterol source and the enzyme preference. Typically, Leydig cells utilize de novo synthesized cholesterol for androgen biosynthesis. However, in cases in which rodents use LDL or HDL as the cholesterol source for androgen biosynthesis, the Leydig cells heavily rely on the SR-BI/selective pathway. In contrast, human Leydig cells utilize the LDL/LDL-receptor endocytic pathway. Moreover, CYP17A1 in rodent Leydig cells acts on 17 α -hydroxyprogesterone (Δ^4), whereas in human Leydig cells it acts on 17 α -hydroxypregnenolone (Δ^5).

Summary

Testosterone biosynthesis is essential for the development of internal/external male genitalia, the establishment of secondary male characteristics, and spermatogenesis. Leydig cells are the primary source of testosterone in the testis. In addition to testosterone, Leydig cells produce other steroids that are essential for male development, including DHT and estradiol.

In Leydig cells, testosterone and other androgens are synthesized from cholesterol derived from different sources. The translocation of cholesterol from OMM to IMM is the hormone-sensitive and rate-limiting step in androgen biosynthesis. Four steroidogenic enzymes catalyze the biosynthesis of testosterone: CYP11A1, 3 β -HSD, CYP17A1, and 17 β -HSD3. After synthesis, testosterone can be further metabolized into DHT, estradiol, androsterone, and 5 α -androstenediol by three enzymes, 5 α -reductase, CYP19A1, and 3 α -HSD. Functionally different from ALCs, FLCs synthesize more DHT to support male sexual development in fetal life.

There are still many unknowns about Leydig cell androgen biosynthesis, particularly so in the human. For example, the origin of human Leydig cells, the identification of individual SLCs, and the cell fate of NLCs all remain to be clarified. Moreover, it is well known that the substrate specificity of cytochrome P450s is limited, and this suggests the presence of alternative unexplored yet substrates for androgen formation (Lieberman, 2008).

Investigating Leydig cell androgen biosynthesis is important in order to understand the underlying mechanisms of male sexual development and the origins of associated developmental defects. Moreover, reduced androgen formation is associated with aging.

Indeed, 20%–50% of men over age 60 are reported to have serum testosterone levels significantly below those of young men (Midzak et al., 2009). Whether in aging or young men, reduced serum testosterone is associated with a number of metabolic and quality-of-life changes, including infertility, erectile dysfunction, obesity, osteoporosis and cardiovascular disease. Greater understanding of the molecular, cellular and biochemical mechanisms of androgen formation could lead to the design of methods to induce and control androgen formation.

Introduction

The importance of testosterone for masculinization of the male fetus was established in a series of experiments spanning 100 years from the mid 19th Century to the first half of the 20th century. Arnold Berthold conducted transplantation studies with testes and castrated rooster's, showing that a "secreted substance" restored male behavior and physiological activity (Freeman et al., 2001; Smith et al., 2013). Refining what this substance might be began with observations in freemartin cattle. In cases of twin fetuses with one male and one female fetus, the female fetus was noted to display signs of development of male sex organs, for example the seminal vesicles and epididymis. In two independent studies, Lillie and Keller and Tandler postulated that this resulted from the exchange of a testicular secretion to the female fetus from a male twin, via the placental vasculature (reviewed in Smith et al., 2013). The discovery that this factor was testosterone was made by Jost who in a series of studies between 1947 and 1953 showed that transplantation of a testis into a female rabbit resulted in masculinization, and then demonstrated that the same was true if a crystal of testosterone propionate was used instead, thus defining testosterone as the key hormone driving male development (Josso, 2008).

However, exactly how testosterone was able to mediate its impact on the body remained a mystery for the next three decades. Individuals that were genetically XY, but developed a female body form were well known. In these individuals, gender was classified as female at birth and the first presentation of symptoms tended to be failure of menstruation during puberty, at which time karyotype investigation revealed the presence of a Y chromosome, and further investigation revealed small, internal testes. These individuals produce high levels of testosterone, but for some reason their tissues are unable to respond to this stimulation. The condition was initially called testicular feminization, but more recently is termed complete androgen insensitivity syndrome (CAIS).

An important step on the road to defining why these individuals were unable to respond to testosterone was the identification of a mouse line in a colony at MRC Harwell, Oxfordshire in 1970 (Lyon and Hawkes, 1970). In this curious mouse line, a proportion of males born in the colony developed female sexual characteristics, including a small anogenital distance, nipples, and female sexual behavior. Internally these mice lacked many male reproductive tissues, possessing small testes, that had failed to descend into the scrotum, but lacking seminal vesicles, epididymides and a prostate; a phenotype very similar to CAIS individuals. The gene responsible for this was mapped to the X-chromosome in these mice and termed the Androgen Receptor, and the equivalent human X-chromosome gene was eventually identified and cloned in 1988 (Lubahn et al., 1988).

Androgen Receptor Gene and Protein

Gene Structure and Expression

The gene for the androgen receptor (AR) contains eight exons, spanning 150 kb, and is a single copy gene in men, while woman utilize one functional copy of the gene, due to X-inactivation. Exon one codes for the structurally flexible amino-terminal domain (NTD); exons 2 and 3 for the DNA binding domain (DBD); exon 4 a flexible hinge linking the DBD with the ligand binding domain (LBD) (exon 4–8). The protein is typically 920 amino acids in a length and has a molecular weight of 110 kDa (Fig. 1).

The promoter sequence lacks a typical TATA box and expression of the receptor gene is driven by the transcription factor Sp1, which binds upstream of the transcription start site and at multiple sites within the 5'UTR (reviewed in Hunter et al., 2017). The highest expression of the transcript is in reproductive tissues such a prostate and uterus, but high levels of the receptor mRNA have also been detected in liver, kidney, skeletal muscle and adipose tissue. Notably, the androgens testosterone and DHT have been found to negatively, or positively, auto-regulate expression of the receptor gene (Hunter et al., 2017). The androgen-dependent regulation of receptor levels is likely to contribute to the tissue-selective responses to testosterone.

Domain Organization

Ligand binding domain

The ligand binding domain (LBD) is located at the C-terminal half of the receptor protein and adopts a globular α -helical folded structure (Fig. 1). The hormones testosterone and dihydrotestosterone (DHT) bind with similar affinity to the largely hydrophobic ligand binding pocket, but demonstrate distinct dissociation rates that accounts for the increased potency of DHT (Askew et al., 2007; McEwan, 2013). Selectivity for androgenic steroids is mediated by a limited number of specific amino acid-steroid interactions, involving hydrogen bonding with residues asparagine 706, glutamine 712, arginine 753 and threonine 878 and hydrophobic interactions with leucine 705, methionine 746 and phenylalanine 747 (McEwan, 2013).

Hormone binding results in a conformational change in the LBD, leading to a more compact structure and the positioning of helix 12 to create a surface pocket important for intramolecular interactions with the amino-terminal domain (NTD) of the receptor and co-regulatory proteins (AF2, Fig. 1). A recent study characterized for the first time a surface on the LBD that leads

Human Androgen Receptor Gene

Human Androgen Receptor Protein

Fig. 1 Androgen receptor gene and protein structure. Top panel shows a schematic representation of the human androgen receptor gene. The protein codon exons (1–8) are colored to match the domain structure of the protein (bottom panel). The bent arrow represents the transcription start site (+1). Bottom panel shows the structural and functional domains of the receptor protein. LBD, ligand binding domain; DBD, DNA binding domain; and NTD, amino-terminal domain. Activation functions (AF) 1 and 2 are also indicated.

to homo-dimerization of the AR-LBD (Nadal et al., 2017). This involved amino acids in helices 5, 7–9 and intervening loops (Fig. 1). Of particular significance is that a number of receptor point mutations associated with androgen insensitivity syndrome (AIS) or prostate cancer map to this large dimerization surface (Nadal et al., 2017).

DNA binding domain/hinge region

The DNA binding domain (DBD) is a helical domain linked to the LBD by a flexible hinge of 40 amino acids. The latter contains a bipartite nuclear localization signal ($^{629}\text{RKLKK}^{633}$) that is necessary for translocation of the receptor into the nucleus (see below). Folding of this domain is dependent upon the coordination of two zinc ions and results in the formation of a “recognition helix” that fits into the major groove of DNA double helix and mediates specific receptor-DNA interactions. In addition, a sequence of five amino acid forms a loop and acts as a dimerization interface holding two receptor monomers together on the DNA.

N-terminal domain

The N-terminal domain (NTD) represents more than half the receptor protein and in contrast to the LBD and DBD has a flexible, intrinsically disordered, structure (McEwan, 2012). This region of the receptor has a propensity to form α -helical structure and is essential for receptor action by establishing multiple protein–protein interactions inside the cytoplasm and nucleus of the cell (see below).

Within the AR-NTD are a number of polymorphic repeats sequences coding for the amino acids glutamine (CAG), glycine (GGC) and proline (CCC,CCG,CCT). The largest poly-glutamine repeat varies between 9 and 38 in the normal population and expansion to greater than 40 residues is associated with reduced function, protein aggregation and results in Kennedy’s disease, a neurodegenerative condition (La Spada et al., 1991).

The importance of the AR-NTD has been further demonstrated by the recent identification of splice variants, lacking the LBD in castrate resistant prostate cancer (CRPC) (reviewed in McEwan, 2012). These receptor polypeptides contain the NTD and DBD, but have unique C-terminal sequences and arise from the splicing of cryptic exons within the AR gene.

Receptor Posttranslational Modifications

Posttranslational modification of proteins is a common feature in eukaryotic cells and an important mechanism for controlling protein function, localization and stability. The androgen receptor is subject to phosphorylation primarily on serine residues and acetylation, methylation, sumoylation or ubiquitination on lysine residues. The functional consequences of specific modification of individual amino acids is an ongoing area of research, but in general terms these changes can alter receptor intracellular trafficking, hormone-dependent transcription and protein turnover.

Classical Androgen Receptor Signaling

In the absence of hormone, the receptor is located in the cytosol as part of a multiprotein complex with chaperones (Hsp 90, Hsp 70) and cochaperones (FKBP51) (**Fig. 2**). This complex is critical for maintaining the AR in a “fit state” to bind the steroid hormones testosterone or the more potent DHT. The binding of hormone causes conformational changes in the receptor protein: “helix 12” in the LBD re-aligns, closing off the ligand binding pocket, often referred to as a mouse trap action; and the nuclear localization signal (sequence of basic amino acids) in the hinge is exposed, allowing interactions with the cell’s transport network (motor protein dynein, microtubules tracks, importin proteins) and translocation to the nucleus.

The binding of hormone also permits dimerization of the receptor. In the cytosol this is thought to involve inter-molecular interactions between an amino acid sequence, ²³FngLF²⁷, in the AR-NTD and the AF2 pocket on the surface of AR-LBD (**Fig. 2**) (**van Royen et al., 2007**). This is referred to as the N/C-terminal interaction, which maybe unique to the mechanism of action of the AR (**Langley et al., 1995**). Once in the nucleus receptor dimers can be stabilized through the recently described surface on the LBD and the D-box region in the DBD. Binding to DNA can disrupt the N/C-terminal interaction (**van Royen et al., 2007**) opening up regions of the AR-NTD for interactions with the cellular transcriptional machinery (**Fig. 2**).

Early in vitro studies defined two classes of AR DNA binding site: hormone response elements (HRE) that were also bound by the glucocorticoid and progesterone receptors and more selective androgen response elements (ARE) only functional with the AR DBD. In an in vivo model, the SPARKI (specificity-affecting AR Knock-in) mouse, where the AR DBD was swapped for the GR the impact on male development and gene expression and fertility were observed (**Schauwaers et al., 2007**). These elegant studies demonstrate a role for AR-selective AREs in the development of male reproductive tissues and fertility, but not in other tissues.

Genome wide studies, involving chromatin immunoprecipitation (ChIP) and ChIP-seq, have largely confirmed the 15 bp consensus binding site for the AR made up of 6 bp half sites: 5'-GGA/TACAnnnTGTTCT-3'. However, these studies have also revealed that the receptor can recognize and bind variations consisting of single or multiple half-sites. Importantly, these studies have also allowed the identification of key transcription factors that participate in androgen-dependent gene regulation, including GATA2, FOXO1, ETS1 and AP1 (**Bolton et al., 2007; Mills, 2014**). Interestingly, interactions with pioneering transcription factors may lead to reprogramming of AR gene targets in progression of prostate cancer to a hormone-resistant stage (**Mills, 2014**). Binding sites for the receptor are typically located within 1 Kbp of the transcription start site and often within the promoter sequences. However, some binding sites can be located in enhancer regions several kbp from the start site e.g., prostate specific antigen gene. Genome-wide expression (RNA-seq) experiments has also revealed networks of genes up- or down-regulated in response to hormone in different cells and tissue. These include genes involved in development, cell growth and cell cycle regulation and metabolism (**Bolton et al., 2007; Mills, 2014**).

Fig. 2 Classical mechanism of androgen receptor action. In the absence of hormone, the androgen receptor is predominantly found in the cytosol complexed with molecular chaperones and associated proteins (Chaperone complex). Upon binding hormone, the receptor dissociates and the N/C-terminal interaction occurs between FngLF motif and AF2 pocket on the LBD, the hormone bound receptor then translocates to the nucleus and binds specific DNA response elements associated with target genes. The receptor complex can then recruit coregulator proteins, which modify chromatin structure or directly recruit RNA Polymerase II (Coregulator complex).

Mechanisms of transcriptional regulation can involve opening or closing of chromatin structure and/or the recruitment of coactivator or corepressor complexes and the cell's transcriptional machinery. The AR interacts with a large number of potential coregulatory proteins, including histone modifying enzymes (e.g., LSD1, Set9), coactivators/repressors (e.g., SRC-1,2, and 3/SMRT) and general transcription factors (e.g., TFIIF, TFIID) (Fig. 2) (Reviewed in McEwan, 2012).

Methods of Dissecting Androgen Receptor Function

One of the major complexities surrounding the dissection of AR function is the myriad of roles it plays throughout the body. The classic approach to dissecting gene function in physiology is to knock it out in mice and study the resulting phenotype. However, as we have seen with the testicular feminized mouse, and which was repeated when an *Ar* knockout mouse was produced (Yeh et al., 2002), the essential role of the AR in normal male development means that male tissues do not develop or are secondarily impacted, making it extremely difficult to study the specific roles for AR signaling in tissues and cells. This problem was successfully addressed in 2004, with the publication of mouse models in which conditional gene-targeting was exploited to knock-out AR in individual testicular cell-types (reviewed Smith and Walker, 2014).

To achieve this, scientists exploited the Cre-Lox system of conditional gene targeting. In this system, the target gene (androgen receptor) is genetically modified with the addition of two target loxP sites placed within introns of the gene. Under normal conditions these introns are naturally spliced out when an mRNA is produced, thus the animal develops and functions completely normally. However, these target sequences are recognized by a Cre Recombinase protein, which causes recombination between the two target sites, essentially snipping out the intervening DNA sequence. By placing these target sequences either side of a key exon, and then controlling which cell-type expressed the Cre Recombinase (by placing the gene for this protein downstream of a cell-specific promoter) researchers were able to selectively knockout the androgen receptor in specific cell or tissue types. To date at least five different alleles of androgen receptor have been targeted for deletion in this way (reviewed in Smith and Walker, 2014), and these have been used to determine the cell-specific role of androgen receptor in all cell types of the testis and male reproductive tissues, as well as many peripheral tissues.

Androgen Receptor Signaling in the Testis

AR is widely expressed in testis tissues, present in all somatic cell types, yet absent from germ cells. This means that the impact of testosterone, which we know to be essential for spermatogenesis, must be mediated by signaling in somatic cells. Selective AR knockout from somatic cell-types has permitted dissection of these roles and attribution of impacts of AR signaling on each cell-type. AR signaling functions in Sertoli cells to support postmeiotic germ cell development. Given their close proximity and the role of Sertoli cells as "nurse cells" this is perhaps predictable, however what was surprising was the finding that loss of Sertoli cell AR reduced the final Leydig cell populations size by 40% (De Gendt et al., 2005). Further targeting studies demonstrated that AR signaling in Peritubular myoid cells supported all stages of spermatogenesis, but also, Sertoli cell function and Leydig cell development, whilst Leydig cell AR signaling was essential for maturation of the Leydig cell population and function in adult life. Together these separate reductionist approach studies uncovered a far more complex and intertwined network of androgen interactions in the testis, than previously thought.

One of the caveats of this approach is that the timing of AR knockout is dependent upon the onset of Cre Recombinase expression. In the case of Sertoli cells for example, use of the *Amh*-Cre line which is active from embryonic day 13 means that Sertoli cells develop having never been exposed to androgen receptor signaling. This makes it challenging to dissect developmental from adult function effects. To address this a variation on this approach, encoding the Cre Recombinase gene within a lentivirus which is injected into the efferent ducts has allowed the induction of AR knockout in Sertoli cells only in adulthood. This has confirmed that AR action inside Sertoli cells in adulthood is essential for spermatogenesis and male fertility (Willems et al., 2015). Additional research on the role of androgen receptor in other cells of the testis in adulthood is ongoing.

To further our understanding of AR action, ectopic activation of AR expression has also been used to enhance our understanding of its normal role. Prematurely expressing androgen receptor in mouse Sertoli cells from fetal life (it normally switches on at post-natal day 4), leads to premature maturation of the Sertoli cell (and Leydig cell) populations, inextricably linking androgen receptor to a role in testicular maturation (Hazra et al., 2013). Together these approaches, selective ablation, or activation of AR, have provided, so we thought, a complete dissection of the role of AR signaling in both reproductive and other tissues, however, a recent observation has shown us we have much yet to learn.

Nonclassical Androgen Receptor Signaling

Because AR functions as a transcription factor, our molecular understanding of the role of testosterone has been established through identification of AR target genes, identified due to the presence of androgen response elements (ARE) within their promoters. Changes in gene transcription can take hours to demonstrate a physiological response, and yet in 2004, isolated Sertoli cells were shown to rapidly respond to testosterone stimulation within a minute, by upregulating activity of MAP-kinase signaling, and that this required androgen receptor.

This paradigm shifting observation suggested that AR is able to act in a nonclassical manner to affect physiological change, however whether testosterone acts via this pathway in vivo remained a mystery until 2016. Ironically, although we have learnt much from the cell-specific ablation models of AR in mice, the very nature of how this system works disrupts both classical and nonclassical signaling pathways simultaneously. In a groundbreaking study, (Toocheck et al., 2016) utilized specific activators and inhibitors of either classical or nonclassical AR signaling in Sertoli cells in mice to show that both pathways share overlapping functions, yet also distinct roles during spermatogenesis, and that nonclassical AR signaling (in addition to classical AR signaling) is essential for male fertility. This work identified, that a meiotic block in sperm development occurs if the nonclassical pathway is specifically inhibited, even if the classical AR signaling pathway is working. This finding alone has changed the way we view AR signaling. It is highly likely that this pathway is active in many cell-types of the body, with possible implications not only under normal conditions, but possibly for our understanding of AR signaling in disease.

Summary

In conclusion, since it was first cloned in 1988, our understanding of the critical roles of androgen receptor in both reproductive and nonreproductive tissues has continued to expand. The recent confirmation of novel modes of action of androgen receptor means there is still much yet to learn. Future studies will exploit this advance in our fundamental understanding to inform our knowledge and suggest treatment options in situations of pathology, for example disorders of sexual development and testis cancer and prostate cancer.

Nongenomic Androgen Actions in Male Reproductive Tissues

Nongenomic Steroid Actions

The classic genomic mechanism of steroid action entails diffusion of steroids into target cells where they bind to intracellular receptors belonging to the nuclear receptor superfamily, causing receptor dimerization and translocation to the nucleus. The steroid-bound receptor dimer acts as a transcription factor by binding to specific DNA-sequences called hormone response elements on the regulatory regions of genes and recruiting co-regulator proteins which results in alterations in the rates of gene transcription. This genomic mechanism of steroid action, involving new mRNA and protein synthesis, is relatively slow with functional responses typically occurring over a period of several hours to days. In addition, there is substantial evidence that steroids also bind to steroid receptors on the cell surface or inside the cell membrane to rapidly activate intracellular signaling pathways resulting in fast hormonal responses. These rapid responses are nongenomic because they are not blocked by inhibitors of transcription and translation and involve activation of second messengers (Levin, 2011; Thomas, 2012). Rapid changes in signaling involving adenylyl cyclase (AC), epidermal growth factor receptor (EGFR), mitogen-activated protein kinases (MAPkinases), extracellular-regulated kinases 1 and 2 (ERK1/2), phosphatidylinositol 3-kinase (PI3K), Akt, Ca^{2+} , and diacylglycerol (DAG) have been reported after steroid treatments. For example, testosterone treatment increases Ca^{2+} levels in Sertoli cells within 20 s (Rahman and Christian, 2007), and progesterone hormones increase cyclic adenosine monophosphate (cAMP) levels in teleost sperm and induce sperm hypermotility within 1 min (Thomas, 2012). This induction of fish sperm hypermotility is through a nongenomic mechanism because it is too rapid to be mediated by a genomic mechanism. However, rapid steroid activation of second messenger signaling can also ultimately lead to genomic responses. Testosterone activation of MAPkinase in Sertoli cells causes rapid phosphorylation of the transcription factor, cAMP response element binding protein (CREB), and upregulation of several CREB-regulated genes (Rahman and Christian, 2007). Similarly, testosterone upregulation of proapoptotic genes in prostate cancer cells through activation of a cell membrane receptor is mediated through MAPkinase activation (Thomas et al., 2014). Since all these nonclassical steroid actions are initially mediated through activation of second messenger signaling pathways the term nongenomic will be used in this article to describe them.

Receptors Mediating Nongenomic Steroid Actions

Nuclear Receptors

Nongenomic steroid actions are mediated by membrane receptors or binding proteins located on the cell surface or by receptors tethered to the inside of the cell membrane and at other extranuclear locations (Levin, 2011). Nuclear receptors for all the major classes of steroids have been shown to be intermediaries in nongenomic steroid actions initiated at these extranuclear locations. Ligand binding to nuclear androgen, estrogen and progesterone receptors (ARs, ERs, and PRs) in a variety of reproductive tissues enables them to associate with Src (intracellular tyrosine kinase) resulting in activation of Src kinase and EGFR dimerization and activation (transactivation) which in turn initiates MAPkinase signaling. On the other hand, epidermal growth factor (EGF) phosphorylates ER in breast and prostate cancer cells through EGFR and Src to stimulate the formation of a signaling complex between EGFR, AR/ER, and Src (Migliaccio et al., 2006). Thus, rapid, nongenomic steroid signaling may involve complex interactions between nuclear receptors and between EGF/EGFR and the nuclear steroid receptor/Src complex. Nuclear steroid receptors have also been detected on the surface of cells using specific antibodies and shown to be activated at the cell surface using steroid-protein complexes that cannot enter cells. Palmitoylation of ERs and ARs increases their association with caveolin-1 resulting in transport of a small proportion of the receptors to the plasma membrane where they are localized in caveolae (Levin, 2011). Membrane-associated nuclear receptors have also been shown to transduce steroid signals intracellularly by the same mechanism as members of the G protein-coupled receptor (GPCR) superfamily, through activation of G proteins. For instance, the membrane-bound ER ($\text{ER}\alpha$) induces rapid intracellular signaling pathways and nitric oxide production in rodent vascular cells through activation of an inhibitory G-protein. In addition, truncated forms of ERs such as $\text{ER}\alpha 46$ and $\text{ER}\alpha 36$ have shown been to mediate nongenomic steroid signaling.

Membrane Receptors

Rapid steroid activation of intracellular signaling pathways resulting in nongenomic responses has also been demonstrated in cells that lack nuclear steroid receptors. In addition, many nongenomic steroid actions in vertebrate cells are not modulated by specific nuclear steroid receptor agonists and antagonists. Furthermore, the biochemical binding characteristics of steroid receptors detected on the plasma membranes of numerous cell types differ from those of the nuclear steroid receptors. Taken together, these findings suggest the existence of distinct steroid membrane receptors unrelated to nuclear steroid receptors. Different steroid membrane receptors for estrogens, androgens and progestins have been identified in the past 15 years. A 7-transmembrane progesterone receptor that mediates progesterone induction of oocyte maturation by a nongenomic mechanism, named membrane progesterone receptor alpha

(mPR α), was discovered in 2003 in fish ovaries (Thomas, 2012). Altogether, five closely-related membrane progesterin receptors (mPR- α , - β , - γ , - δ , - ϵ) have been identified in vertebrate tissues. Although the mPRs are coupled to G proteins they do not belong in the GPCR superfamily and instead are members of the progesterin adipoQ receptor (PAQR) family. Progesterin activation of G proteins through mPRs results in alterations of intracellular signaling through various pathways including those involving cAMP, Ca²⁺, PI3K, MAPkinase, and EGFR. The mPRs mediate a wide variety of progesterin reproductive actions including initiation of sperm hypermotility, oocyte meiotic maturation, inhibition of cell death and apoptosis of ovarian follicle cells, and reproductive behaviors (Thomas, 2012). In 2005, the orphan 7-transmembrane GPCR, GPR30, was shown to have all the characteristics of an estrogen membrane receptor in an ER-null breast cancer cell line. GPR30 is coupled to G proteins and stimulates similar intracellular signaling pathways to those activated through the mPRs. The functions of GPR30, now known as G protein-coupled estrogen receptor (GPER), have been studied extensively and implicated in a broad range of physiological and pathological actions of estrogens and xenoestrogens including proliferation of numerous cell types, and tumorigenesis. GPER has an important role in the maintenance of oocyte meiotic arrest in fish. On the other hand, only a few reproductive functions of GPER such as regulation of GnRH secretion and spermatogonial cell proliferation have been identified in mammals and GPER knockout mice are fertile and display few reproductive abnormalities. A third novel steroid membrane receptor, the membrane androgen receptor, ZIP9, has been recently discovered in fish ovaries. ZIP9 is a 7–8 transmembrane protein belonging to the ZIP (ZRT- and Irt-like Protein, SLC39A) family that transports zinc across the cell membrane and from organelles into the cytoplasm to regulate zinc homeostasis. ZIP9 displays all the binding characteristics of a novel androgen receptor in both fish ovarian follicle cells and in breast and prostate cancer cells and is coupled to G proteins (Thomas et al., 2017). The occupied receptor induces apoptosis in both ovarian and cancer cells through the intrinsic pathway, involving upregulation of Bax, P53, JNK, and Caspase 3. Interestingly, testosterone induces both MAPkinase activation and zinc influx through ZIP9 in a G protein-dependent manner and testosterone's apoptotic action is dependent on both of these responses. Thus, ZIP9 acts as a membrane androgen receptor and a zinc transporter, with both these functions being required for the androgen-dependent apoptotic response.

Other Steroid Binding Proteins

A diverse variety of other proteins, including steroid hormone binding globulins (SHBG), ion channels, receptors for other hormones and adaptor proteins have also been proposed to have important roles in rapid steroid signaling. For example, androgens bound to SHBG can activate the SHB receptor on the cell surface of Sertoli cells leading to G protein and AC activation. Moreover, androgens have been shown to antagonize the activation of the eicosanoid receptor by its natural ligand in prostate cancer cells. The CatSper channel mediates the progesterone-induced Ca²⁺ increase in human sperm. In addition, progesterone membrane component one (PGRMC1) has an important adaptor protein function in nonclassical progesterone signaling through regulation of mPR expression on the plasma membrane.

Nongenomic Androgen Actions in Male Reproduction

Nongenomic actions of estrogen and progesterone have been studied extensively in a wide variety of cell types. Moreover, the nuclear and membrane receptors that mediate many of these rapid estrogen and progesterone effects have been identified and are the subject of several recent reviews. In comparison, relatively few studies have been conducted on nongenomic androgen actions in vertebrate cells and the identity of an androgen membrane receptor was unknown until a few years ago. Recently, convincing evidence has been obtained for nongenomic androgen actions and androgen-dependent signaling in male reproductive tissues (Rahman and Christian, 2007; Walker, 2010). In addition, the novel membrane androgen receptor, ZIP9, was recently discovered and identified in both the male and female reproductive systems (Thomas et al., 2014). Androgens have an indispensable role in the regulation of male reproduction and are essential for development of the male reproductive system, normal spermatogenesis and fertility. Here rapid androgen signaling and nongenomic actions in the male reproductive system and the receptors mediating these responses will be briefly reviewed.

Sertoli Cells

Androgens, produced in the testis by Leydig cells, are released into the circulation and also diffuse into the seminiferous tubules, the site of spermatogenesis. The Sertoli cells, which surround the germ cells and provide nourishment for their development, perform several of critical functions during spermatogenesis that are regulated by androgens, including maintenance of the blood–testis barrier, meiosis, attachment of Sertoli cells to spermatids, and sperm release. Studies with AR mutant mice that lack the androgen response element (ARE) specific for androgens have shown that classic genomic androgen actions through selective AREs are required to support complete spermatogenesis and for the regulation of numerous genes in Sertoli cells. However, the results of recent studies suggest several rapid, nongenomic androgen actions on Sertoli cells involving a variety of signaling pathways and receptors also contribute to germ cell development.

Fig. 1 Nongenomic androgen signaling pathways in Sertoli cells. (1) Testosterone signaling through a Src/EGFR/MAPkinase/p90^{Rsk}kinase/CREB pathway mediated by a membrane-associated AR resulting in upregulation of genes critical for the development and survival of germ cells. LDH: lactic dehydrogenase. (2) Testosterone signaling through a G protein/ERK1/2 pathway mediated by ZIP9 resulting in upregulation of claudin genes essential for tight junction formation and maintenance of the blood–testis barrier. (3) Testosterone signaling through a G protein/PLC-PIP2/K⁺_{ATP}/L-type Ca²⁺ channel mediated by an unidentified membrane androgen receptor (umAR) resulting in Ca²⁺ influx. *Mem.depol.*: membrane depolarization; *solid lines*: regulatory pathways; *hatched lines*: biological responses; *?*: downstream target unknown.

Mediated through membrane-associated AR

Testosterone binding to a subcellular fraction of the AR located near the cell membrane of Sertoli cells causes the receptor to associate with and activate Src tyrosine kinase which in turn phosphorylates the EGFR resulting in its dimerization and activation (transactivation) and the initiation of MAPkinase signaling. ERK1/2 phosphorylation causes activation of p90^{Rsk} kinase which leads to CREB phosphorylation and CREB-regulated transcription. CREB activates a variety of genes in Sertoli cells involved in the development and survival of germ cells, including the AR, insulin-like growth factor 1 (IGF-1), transferrin, and lactic dehydrogenase. The finding that the AR antagonist flutamide blocked CREB phosphorylation suggests this rapid action is mediated through the AR. Furthermore, studies using cultured Sertoli cells with an AR mutant that can only activate rapid androgen signaling show that this signaling pathway participates in the adhesion of Sertoli cells to germ cells which is important for the maintenance of spermatogenesis (Walker, 2010; Fig. 1, pathway 1).

Mediated through ZIP9

The results of recent studies suggest testosterone activation of rapid, nongenomic signaling in Sertoli cells is also mediated through the novel membrane androgen receptor, ZIP9, which also functions as a zinc transporter. Evidence was obtained that ZIP9 is an intermediary in androgen maintenance of the blood–testis barrier. The blood–testis barrier is indispensable for spermatogenesis by providing an immune-privileged microenvironment for the completion of meiosis. Androgen regulation of claudin production and tight junction formation by Sertoli cells are required for preservation of the blood–testis barrier. This testosterone action is not mediated through the AR because it can also be demonstrated in an AR-deficient Sertoli 93RS2 cell line. Low concentrations of testosterone caused rapid phosphorylation of ERK1/2, and the transcription factors CREB and ATF-1 in the 93RS2 cells which was accompanied by increased claudin-1 and -5 expression and tight junction formation. Interestingly, all these androgen actions were blocked after knockdown of the expression of ZIP9 with siRNA (Buldan et al., 2016; Fig. 1, pathway 2). Thus, this study provides the first clear evidence for an important role of ZIP9 as an intermediary in androgen regulation of the blood–testis barrier which has important implications for completion of spermatogenesis and male fertility. However, the physiological role of androgen-mediated zinc signaling through ZIP9 in Sertoli cells and possible cross-talk with AR-dependent signaling have not been investigated.

Mediated through unidentified membrane androgen receptor

A third rapid androgen-dependent pathway involves a rapid influx of Ca^{2+} into rat Sertoli cells and increased input resistance and depolarization through an androgen receptor on the cell membrane (Loss et al., 2004; Fig. 1, pathway 3). The identity of this receptor remains unresolved and has been proposed to be the AR (Rahman and Christian, 2007), or an unidentified receptor (Walker, 2010), based on positive or negative results with AR-specific ligands, respectively. Experiments using pharmacological tools have shown these androgen effects are dependent on activation of a pertussis toxin-sensitive G protein, blockage of the $\text{K}^{+}_{\text{ATP}}$ channel and activation of phospholipase C (PLC). PLC activation hydrolyses phosphoinositol (PIP2) to inositol triphosphate (IP3) and DAG. The depletion of PIP2 stores (also likely the increase in DAG) stimulates closure of the $\text{K}^{+}_{\text{ATP}}$ channels resulting in increased input resistance and depolarization which in turn opens voltage-dependent L-type Ca^{++} channels, enabling Ca^{++} influx (Loss et al., 2004). Currently, the physiological significance of this androgen signaling pathway is unclear.

Prostate Cells**Mediated through membrane-associated AR splice variant**

A wide variety of nongenomic androgen actions and signaling pathways activated through the AR and membrane androgen receptors have been reported in prostate cancer cells. Androgens also have critical functions in the prostate gland, regulating its development and maintenance. In addition, androgens have a major role in promoting the initial stages of prostate cancer. Progression from the androgen-sensitive to the castration-resistant stage of prostate cancer is regulated by the AR and its splice variants. The ineffectiveness of AR antagonist therapy during this castration-resistant stage severely limits the therapy options during the advanced stages of prostate cancer. An AR splice variant cloned from prostate cancer tissues, AR8, lacks a DNA binding domain and is primarily localized on the plasma membrane. Overexpression of AR8 in LNCaP prostate cancer cells has been shown to cause association of AR and Src with EGFR in response to EGF treatment and increase AR phosphorylation. In contrast, these EGF responses are blocked by knockdown of AR8 expression in prostate cancer cells and are accompanied by decreases in cell proliferation and increases in apoptosis of cells cultured in an androgen depleted medium. Collectively, these results suggest that the AR splice variant AR8 located on the plasma membrane of prostate cancer cells is involved in castration resistance by promoting AR proliferative and survival responses to growth factors and hormones (Yang et al., 2011).

Mediated through membrane-associated AR

Growth factors such as EGF interact with nuclear steroid receptors to promote ligand-independent steroid receptor-regulated transcription resulting in the growth and proliferation of cells and breast and prostate cancer progression. However, the crosstalk is bidirectional because activation of nuclear steroid receptors greatly increases EGF signaling through a nongenomic mechanism in both breast and prostate cancer cells. EGF stimulation of cytoskeletal changes and DNA synthesis are blocked by treatment with ER and AR antagonists in LNCaP cells, which suggests both ERs and AR are components of these EGF-mediated actions. Interestingly, a small proportion of the ER β (ER β) and AR are associated with each other under these prostate cancer cells under unstimulated conditions. EGF promotes phosphorylation of tyrosine residues on ER and stimulates the formation of a complex between EGFR, AR, ER β , and Src tethered to the cell membrane which is required for Src activity, EGFR phosphorylation and the growth stimulatory effects of EGF (Migliaccio et al., 2006). Taken together these results show reciprocal regulation of EGF- and nuclear steroid receptor/Src-mediated signaling in prostate cancer cells through a multiple nuclear steroid receptor/Src/EGFR protein complex. Another study showed that the scaffold protein MNAR (modulator of nongenomic activity of estrogen receptor) co-precipitates with the AR and Src which suggests it may be part of the EGFR/ER/AR/Src signaling complex.

Nongenomic androgen activation of ERK1/2 signaling in AR-positive LNCaP cells is mediated through matrix metalloproteinase (MMP) regulation of EGFR transactivation. Knockdown studies with paxillin siRNA have indicated an essential role for this multi-domain adaptor protein in androgen- and EGF-induced ERK1/2 signaling in LNCaP and in AR-null PC-3 cells, respectively, and also in the proliferation, migration and invasion of these cancer cells. Evidence was obtained that EGFR transactivation stimulates Src-induced phosphorylation of specific paxillin tyrosine residues which in turn promotes ERK1/2-mediated phosphorylation of several paxillin serine residues and the proliferation response. The finding that ERK1/2-mediated transcription in these cells is dependent on paxillin phosphorylation suggests that paxillin may enhance ERK1/2-mediated proliferation in these cancer cells by stimulating ERK1/2-regulated transcription (Sen et al., 2010).

A subpopulation of the AR is localized to the lipid raft compartment in LNCaP cells where it interacts with Akt1. This interaction is increased by androgen treatment resulting in elevated Akt1 activity, whereas it is blocked by the AR-antagonist, bicalutamide. Interestingly, this rapid increase in Akt1 activity does not involve PI3K signaling. The results suggest lipid rafts function to transmit nongenomic androgen signals through the AR and Akt pathway in these cancer cells.

Mediated through unidentified membrane androgen receptors unrelated to AR

Androgens also induce nongenomic actions in prostate cancer cells through membrane receptors unrelated to nuclear steroid receptors. Androgen binding to the cell surface of LNCaP cells has been detected by confocal microscopy using the membrane impermeable testosterone conjugate, T-BSA-FITC. Although testosterone-BSA phosphorylates ERK1/2 in LNCaP cells, it does not significantly activate two other MAPkinases, p38 MAPK and JNK. Treatment with the AR antagonist cyproterone did not blunt the ERK1/2 phosphorylation response to testosterone-BSA which suggests this nongenomic action is not mediated through the AR but instead through an unidentified membrane receptor (Wang et al., 2008). Activation of ERK1/2 is associated with an

increase in the concentration of the c-Fos protein which is a constituent of the AP1 transcription factor that regulates the growth and transformation of cells, and therefore, may have a major role in prostate cancer development.

Rapid androgen signaling initiated at the cell surface resulting in actin cytoskeleton reorganization, inhibition of cell proliferation, motility, and adhesion, as well as induction of apoptosis has been described in LNCaP (AR positive) and DU145 (AR-deficient) prostate cancer cells. This nongenomic androgen action is clearly not mediated by the AR in LNCaP cells because it is not altered by treatment with AR antagonists such as flutamide or by treatment with AR siRNA (Hatzoglou et al., 2005; Papadopoulos et al., 2009). Androgen activation of an unidentified membrane androgen receptor in LNCaP cells triggers a signaling pathway involving activation of focal adhesion kinase (FAK), PI3K, rho small GTPases, and Rho-associated protein kinase (ROCK) which results in actin polymerization and ultimately apoptosis. Although small GTPases (Rho A, Rho B and Cdc42) and ROCK signaling were also shown to regulate actin reorganization in DU145 cells, the results suggest that it is not mediated by activation of the FAK/PI3K pathway. Instead, down-regulation of the pro-survival FAK/PI3K pathway was observed 12–24 h after testosterone treatment (Papadopoulos et al., 2009). The resulting apoptosis in DU145 cells is likely mediated by an intrinsic pathway because it is associated with increased Caspase 3 activity. Testosterone-mediated PI3K and ROCK signaling in DU145 cells also upregulates serum- and glucocorticoid-inducible kinase (SGK1) which in turn activates Na^+/H^+ exchangers and increases intracellular pH (Chatterjee et al., 2014). The finding that treatment with an inhibitor of Na^+/H^+ exchanger activity blocked actin polymerization in response to testosterone treatment suggests an involvement of these exchangers in actin reorganization mediated by a membrane androgen receptor.

Androgens also induce rapid and transient L-type calcium channel-dependent increases in intracellular Ca^{2+} levels in LNCaP cells through a receptor on the cell surface associated with a pertussis toxin-sensitive G protein, suggesting it is coupled to an inhibitory G protein. This androgen action was not blocked with the AR antagonist, cyproterone acetate, which suggests it is mediated through an unidentified membrane receptor unrelated to the AR (Sun et al., 2006).

Mediated through ZIP9

Nongenomic androgen signaling mediated by the membrane androgen receptor ZIP9 has been clearly demonstrated in AR-null prostate cancer (PC-3) and breast cancer cell lines (MDA-MB-231 and MDA-MB-468) as well as in AR-positive LNCaP cells (Thomas et al., 2014, 2017). Gain of function studies conducted with PC-3 and MDA-MB-231 cells overexpressing ZIP9, as well as loss of function experiments in MDA-MB-468 and LNCaP cells in which ZIP9 expression was knocked down with siRNA show that membrane androgen receptor binding, and androgen signaling and apoptotic actions in these cells are dependent on cell surface expression of the ZIP9 protein. The ZIP9 protein displays high affinity, specific androgen binding to the plasma membranes of these cells with characteristics typical of membrane androgen receptors. ZIP9 has low binding affinities for several AR agonists and antagonists. Testosterone treatment (10–20 nM) specifically phosphorylates ERK1/2 and increases intracellular zinc concentrations through ZIP9 in these cancer cells, both of which are required for an apoptotic response. Interestingly, both androgen-dependent MAPkinase and zinc signaling are mediated through activation of a G protein. Several lines of evidence suggest ZIP9 is coupled to an inhibitory G protein (Gi) in these cancer cells. Firstly, pertussis toxin pretreatment blocks MAPkinase and zinc signaling as well as apoptosis in response to testosterone treatment. The finding that testosterone treatment causes decreased cAMP production in ZIP9-transfected cells is also consistent with activation of a Gi protein. Finally, an in situ proximity ligation assay revealed a close association of ZIP9 with a Gi in ZIP9-transfected PC-3 cells. Testosterone induces ZIP9-mediated apoptosis in prostate and breast cancer cells through upregulation of components of the intrinsic apoptotic pathway, Bax (Bcl-2-associated X protein) and P53 (tumor protein 53), as well as JNK (c-Jun N-terminal kinases) which is involved in both the intrinsic and extrinsic pathways. These increases in gene expression were blocked by pretreatment with either a zinc chelator or a MAPkinase inhibitor, indicating both signaling pathways are required for upregulation of these proapoptotic members. The finding that the concentrations of Bax, cytochrome C and Caspase 3 proteins as well as Caspase 3 activity are also increased after testosterone treatment are consistent with activation of the intrinsic apoptotic pathway (Fig. 2). It is concluded from these studies that ZIP9, a member of the zinc transporter ZIP family, functions as a specific membrane androgen receptor coupled to an inhibitory G protein in prostate cancer cells through which testosterone activates MAPkinase and zinc signaling pathways regulating apoptosis. The discovery that ZIP9 expression is upregulated in invasive malignant cells in prostate cancer biopsy samples further suggests that ZIP9 is a potential therapeutic target for treating prostate cancer.

Spermatogenic Cells

Mediated through ZIP9

A recent study has shown that testosterone rapidly activates ERK1/2, CREB, and ATF-1 in spermatogenic GC-2 cells, through an AR-independent mechanism (Shihan et al., 2015). These androgen-dependent actions are blocked by silencing ZIP9 and the G protein, $\text{G}\alpha 11$. A ligation proximity assay showed a close association between ZIP9 and $\text{G}\alpha 11$, which suggests the G-protein is directly coupled to the receptor. Taken together these results suggest that rapid androgen signaling in the GC-2 spermatogenic cells is mediated through a ZIP9/ $\text{G}\alpha 11$ pathway. The physiological significance of this nongenomic androgen pathway in spermatogenic cells is currently unknown.

Fig. 2 Nongenomic androgen signaling mediated by ZIP9 coupled to an inhibitory G protein that induces apoptosis through the intrinsic pathway in prostate and breast cancer cells. *Mem.perm.*: Membrane permeability increase; *cyt c*: cytochrome *c*; *solid lines*: regulatory pathways; *hatched lines*: biological responses; *?*: downstream target unknown. Note: ZIP9 is also localized on mitochondrial and nuclear membranes (see Thomas et al., 2017).

GnRH-Producing Hypothalamic Cells

Mediated through membrane-associated AR

Androgens have also been shown to activate intracellular signaling pathways through a cell surface-mediated mechanism in neuroendocrine cells. The plasma membranes of immortalized GnRH-secreting murine GT1-7 cells display androgen binding activity and treatment with dihydrotestosterone (DHT) attenuates forskolin upregulation of cAMP production. This inhibitory DHT action is blocked by treatment with hydroxyflutamide and pertussis toxin which suggests it is mediated through activation of the AR and an inhibitory G (G_i) protein, respectively. Western blot analysis with an AR antibody confirmed the presence of an immunoreactive band of the correct size for the AR in plasma membrane fractions of GT1-7 cells. Treatment with testosterone, DHT, or testosterone conjugated to BSA also significantly increased intracellular Ca^{2+} concentrations within 3 min and increased GnRH secretion twofold after 1 h (Shakil et al., 2002). Whereas 24- and 36-h treatments with testosterone and DHT resulted in downregulation of GnRH mRNA levels as reported previously, similar treatments with testosterone-BSA were ineffective which suggests differential androgen regulation of GnRH secretion and mRNA expression through cell-surface mediated nongenomic and intracellular AR-mediated genomic mechanisms, respectively.

Summary

A bewildering diversity of rapid androgen signaling pathways has recently been identified in cells in the male reproductive system, particularly in Sertoli and prostate cells. However, in many cases their physiological significance remains unclear because the functions of these signaling pathways identified in cell lines have not been confirmed by conducting more physiologically relevant studies in tissues and in whole organisms. Clearly, more research in a variety of physiological contexts is required to identify the reproductive functions of these androgen signaling pathways. In addition, knowledge of the potential interactions between these androgen signaling pathways as well as their possible crosstalk with genomic androgen actions will be required for a clearer understanding of the roles of nongenomic steroid actions in male reproductive physiology. Research over the past few years has shown that the novel membrane receptor, ZIP9, is an intermediary in nongenomic androgen actions in Sertoli, prostate, and spermatogenic cells. The involvement of ZIP9 in other rapid androgen actions not mediated through the AR remains to be investigated. This exciting recent progress on nongenomic androgen actions provides a sound basis for future research in this area.

Glossary

Agonist A ligand, usually a small molecule, which binds and activates a receptor protein.

Antagonist A ligand, usually a small molecule, that can bind and switch off receptor activity. Traditional antagonists act as competitive inhibitors for agonist binding.

Anabolic Process of growth and differentiation of cells and increased body mass.

Cachexia Wasting syndrome, associated with loss of weight, muscle atrophy, weakness and tiredness.

SARD Selective androgen receptor degrader.

SARM Selective androgen receptor modulator.

Introduction

The androgen receptor (AR) is a member of the steroid receptor subfamily of nuclear receptors. The binding of the hormones testosterone or the 5 α -reduced metabolite, DHT activate the receptor protein present in the cell cytosol. Binding of hormone leads to conformational changes in the receptor protein, reorganization of bound molecular chaperones and nuclear translocation and receptor dimerization. The precise order and molecular details of these events remain active areas of research and debate. What is less ambiguous is that transport of the receptor to nucleus permits binding to specific DNA sequences in the genome and regulation of androgen target genes. Thus, the AR, primarily acts as a ligand-activated transcription factor, although rapid signaling by hormone can result in recruitment of the receptor protein to the plasma membrane and activation of protein-kinase signaling pathways.

Androgen Receptor Structure–Function

The AR has the structural and functional domain organization typical of members of the nuclear receptor superfamily (**Fig. 1**). The ligand binding domain is made up of 300 amino acids and makes up the C-terminal third of the protein. This domain is highly α -helical and globular in structure and the binding of agonists causes conformation rearrangement of helix 12 and compacting of the structure (**Fig. 1**). The binding of the hormones testosterone or DHT occurs in the ligand binding pocket (LBP) which is buried in the LBD and is lined with hydrophobic residues, reflecting the chemical properties of steroid hormones, and a relatively small number of amino acids that make ligand discriminating interactions including threonine 877 and asparagine 705 with the hydroxyl group at C17 and glutamine 711 and arginine 752 with the oxygen at C3 (**McEwan, 2013**). Binding of agonist results in the formation of pockets on the LBD surface, notably AF2 which is important for protein-protein interactions and a region, BF3, which can bind small molecules and is allosterically linked to AF2 (**Fig. 1**) (**McEwan, 2013**). More recently, a large surface area of 1000 Å² has been characterized, involving helices 5, 7, 8 and 9, strand 1 and intervening loops, which mediates homo-dimerization of the LBD (**Nadal et al., 2017**).

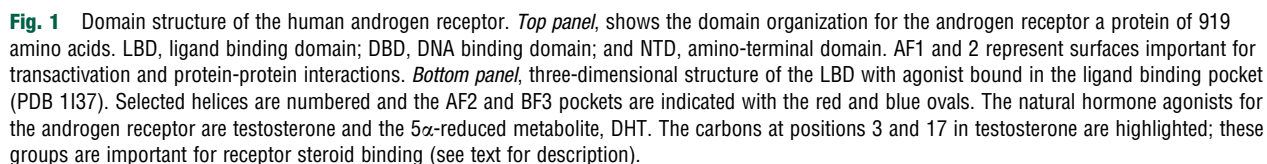

Agonists

Agonists of the Androgen Receptor

Any molecule capable of binding and altering a receptor from its resting state to an activated form, and consequently resulting in a biological response is referred to as an agonist. Agonists can either be endogenous and exogenous.

Endogenous agonists for the AR include the hormones testosterone and DHT (**Fig. 1**) which are naturally synthesized in the body in the gonads and peripheral tissues respectively. As early as the first trimester of fetal development, androgens start to shape the male phenotype by regulating the development of the prostate, scrotum, testes and related organs. After birth, the secretion of androgens ensures the maintenance of these male reproductive organs in addition to facilitating the production of sperm and differentiation of secondary male sex characteristics at puberty and adulthood.

Aside from the reproductive systems, other organs of the body such as the brain, liver, hair follicles, skin, kidney, bone, are also responsive to the effects of androgens. In the brain, behavioral patterns such as mood changes, aggression and cognitive abilities can

Exogenous agonists are synthetic molecules which can be introduced into the body topically, orally or by injection (**Table 1**). Mesterolone, which is used as a replacement therapy to treat males with androgen deficiency or infertility, is an example of an exogenous AR agonist. In addition to androgenic actions, AR agonists can be classed as selective androgen receptor modulators (SARMs) or anabolic androgenic steroids (AAS) (see **Table 1**). Clinically, AR agonists are used to treat osteoporosis ([Snyder et al., 2017](#)), anemia ([Paustian et al., 2016](#)), human immunodeficiency virus wasting syndrome ([Sardar et al., 2010](#)), and hypogonadism in males ([Darby and Anawalt, 2005](#)) (**Table 1**).

Importance of Intracrinology

The gonads, testes and ovaries, are the main sites of testosterone biosynthesis with the weak androgen, dehydroepiandrosterone (DHEA) produced by the adrenal gland. Testosterone (or DHEA) is then transported to target tissue via the blood stream, bound to carrier proteins such as sex hormone binding globulin (SHBG). However, there is increasing evidence for the expression of steroid biosynthetic enzymes in peripheral tissues, such as the prostate, and the importance of intracrinology in the production of testosterone. Inactive precursors such as DHEA, DHEA-sulfate, androstenedione can be converted to testosterone and DHT via tissue specific enzymes such as 3 β -hydroxysteroid dehydrogenase (3 β -OHSD), 17 β -hydroxysteroid dehydrogenase (17 β -OHSD), and 5 α -reductase. The DHT formed is used strictly for intracellular and local actions. About 50% of androgens are made in the prostate while the other 50% are synthesized in the testes (Labrie et al., 2005). Aside from the prostate, the intra-tissue conversion of DHEA to testosterone also takes place in the brain where it affects mood and behavior.

Table 1 Selected synthetic agonists of the androgen receptor

Agonist	Structure	Relative Binding	Action	Uses
7 α -methyl-19-nortestosterone (Trestolone)		260% DHT	ASS	Potential male contraception
Andarine		6% R1881	SARM	Muscle wasting Osteoporosis Performance enhancement
Danazol (Danatrol)		2% DHT	Androgenic	Anaemia Endometriosis
Fluoxymesterone (Halotestin, Ultandren)		0.4% R1881	ASS	Hypogonadism Anaemia (men) Breast cancer (woman)
Mesterolone		25% R1881	ASS	Hypogonadism
Methyltrienolone (R1881)		100 %	ASS	Laboratory studies of AR action
19-nortestosterone (Nandrolone)		32% DHT 60% R1881	ASS	Cachexia Anaemia Osteoporosis
Oxymetholone (Androl, Anapolon)		0.3% R1881	ASS	Osteoporosis Anaemia Cachexia
Oxandrolone (Anavar, Lonavar)		0.3% R1881	ASS	Hypogonadism Osteoporosis Anaemia Cachexia

Table 1 Selected synthetic agonists of the androgen receptor—cont'd

Agonist	Structure	Relative Binding	Action	Uses
Stanozolol (Winstrol, Stromba)		0.8% R1881	ASS	Angioedema Performance enhancement

Relative binding affinity is expressed as percentage of high affinity reference androgen in bracket (DHT or R1881).

These extra gonadal mechanisms of androgen synthesis are of importance in diseases such as prostate cancer where the growth and continued survival of the cancer is highly dependent on the presence of androgens, hence, a knowledge of all the sources of androgens is extremely crucial in informing the choice of treatment of this cancer. Although surgical and medical castration decrease the levels of serum testosterone from about 500 ng/dL to less than 50 ng/dL, androgens are still present within the prostate after castration, hence the use of other interventions such as antiandrogens, 5 α -reductase inhibitors to minimize the levels of androgens (Nishiyama, 2014).

Binding Affinities of Agonists

Ligands of the AR elicit their effects by binding to the ligand binding pocket (LBP) of the ligand binding domain (LBD) of the receptor. The structure of the LBD has been well characterized through crystallography (Fig. 1) which has led to the engineering of many compounds that can interact with the AR as either agonists or antagonists (McEwan, 2013) (Tables 1 and 2). The amino acid residues in the LBP are quite flexible and they make up the interface for the interaction of ligands and the receptor. The hydrophobic residues of the LBP adopt variable positions to fit in the steroid core via Van der Waals interactions, while polar amino acids form hydrogen bonds with polar atoms of the steroids. Collectively these interactions lead to stabilization, specificity and selectivity in agonist binding (McEwan, 2013). Testosterone and DHT bind to the AR with similar binding affinity ($K_D = 0.3\text{--}0.8\text{ nM}$), but the latter ligand dissociates about three to fourfold slower. The binding affinity of an AR ligand is often reported as a relative binding affinity (RBA) which is the measure of the ability of the ligand to competitively displace a high affinity ligand such as DHT or metribolone (R1881). The binding affinities for a selection of synthetic agonists of the AR are shown in Table 1.

Antagonists

Inhibition of the AR has multiple therapeutic indications. AR inhibitors may be employed in the treatment of prostate cancer, acne, seborrhea, hirsutism, androgenic alopecia, polycystic ovarian syndrome, endometrial cancer, and epithelial ovarian cancer. Clinical trials for the efficacy of antiandrogen therapy in triple negative metastatic breast cancer and spinal bulbar muscular atrophy (SBMA) are ongoing (<https://clinicaltrials.gov>). The structures of the clinical antiandrogens outlined below are included in Table 2, alongside their mechanism of action and applications.

Steroidal AR Inhibitors

AR inhibitors, or antiandrogens, can be broadly categorized as steroidal or non-steroidal. A third class of therapeutics, often misnamed antiandrogens, are those which reduce androgen biosynthesis or secretion through effects on the gonads, hypothalamus or pituitary gland, including finasteride, dutasteride and abiraterone, amongst others. Steroidal AR inhibitors often display mixed agonist-antagonist activities, with additional activities at estrogen, progesterone and glucocorticoid receptors mediating an array of side effects.

The first antiandrogen to be used clinically was cyproterone acetate (CPA; Table 2), a competitive AR inhibitor (McEwan, 2013) with additional inhibitory effects on the synthesis of androgens and spermatogenesis. Side effects of CPA are mediated primarily through progesterone and glucocorticoid receptor binding—including decreased basal cortisol and ACTH, and reduced adrenal response to insulin induced hypoglycaemia. CPA is not suitable for pregnant women due to the risk of feminisation of a male fetus, as well as the risk of secondary adrenal insufficiency. Adrenal insufficiency is also a risk in rapid withdrawal due to glucocorticoid receptor mediated suppression of ACTH.

Other steroidal antiandrogens include trimethyltrienolone (RU2956), developed as a derivative of the anabolic-androgenic steroid metribolone (R1881, Table 1). However the coincidental development of non-steroidal antiandrogen flutamide (Table 2) prevented progression of this compound to the clinic. Other steroidal therapies with antiandrogen activity include chlormadinone acetate (CMA), a steroidal progestin with antiandrogen and antigonadotrophic effects and spironolactone, a steroidal antimineralocorticoid with antiandrogen and progesterone effects. Unlike the CPA, these ligands are weak partial agonists of the AR, capable of

Table 2 Structures and mechanisms of androgen receptor inhibitors

Antagonist	Structure	Action	Uses
Apalutamide (ARN-509)		Competitive, non-steroidal antiandrogen	Under development; Phase III clinical trials CRPC
ASC-J9		Hsp90 inhibitor Selective androgen receptor degrader	Experimental inhibitor of androgen receptor signalling
Bicalutamide		Competitive, non-steroidal antiandrogen	Prostate cancer
Cyproterone Acetate		Competitive, steroidal antiandrogen	Prostate cancer
EPI-001		Androgen receptor amino-terminal domain antagonist	Under development; Phase I clinical trials CRPC
Enzalutamide		Second generation, competitive, non-steroidal antiandrogen	Prostate cancer, CRPC
Flutamide		Competitive, non-steroidal antiandrogen	Prostate cancer
Galeterone		Selective androgen receptor degrader Inhibitor of CYP17A1	Under development for prostate cancer; Phase III clinical trials
Nilutamide		Competitive, non-steroidal antiandrogen	Prostate Cancer

competing with testosterone for AR binding and subsequently eliciting a much weaker effect than the endogenous hormone. CMA is also a competitive inhibitor of 5 α -reductase, preventing conversion of testosterone to the more potent DHT. These drugs have never been marketed clinically for diseases driven by the AR.

Non-Steroidal Antiandrogens

Nonsteroidal antiandrogens compete with circulating testosterone and DHT for AR binding, blocking downstream AR dependent gene regulation, but also negative feedback of testosterone action at the hypothalamus and pituitary. This can result in a moderate increase in the baseline levels of plasma testosterone and oestrogens, which in prostate cancer may eventually lead to resistance. Following development of resistance in prostate tumors, antiandrogen withdrawal may result in a short term regression in disease, due to a reduction in negative feedback in the HPA-axis and a subsequent drop in serum androgen concentrations.

The first of the clinically approved non-steroidal antiandrogens, flutamide, was tested preclinically in 1973, showing competitive antagonism of the AR via binding to the ligand binding domain (LBD), and entered clinical trials in 1975. However, due to hepatotoxicity, clinical preference for prostate cancer is now bicalutamide (see below). Derivatives of flutamide include hydroxyflutamide and nilutamide, both of which competitively inhibit binding of testosterone to the AR. The antiandrogen nilutamide (Table 2) was approved for use in Europe in 1987. However its clinical use has been limited by its toxicity profile, most notably a high incidence of interstitial pneumonitis. Another non-steroidal antiandrogen was also described in 1973, but never marketed; DIMP (*N*-(3,5-dimethyl-4-isoxazolylmethyl)phthalimide) was a weakly competitive AR inhibitor structurally related to thalidomide.

Bicalutamide (Table 2) was developed as a more selective antiandrogen, capable of selectively inhibiting peripheral AR with reduced effects on negative feedback loops in the hypothalamus and pituitary, possibly due to reduced blood brain barrier penetration. The affinity of bicalutamide for the AR was found to be four times greater than that of hydroxyflutamide, and in vivo dosing did not cause an increase in serum testosterone. Bicalutamide progressed to the clinical trials under the brand name Casodex in 1989 and received approval for use by the FDA in 1995. Bicalutamide remains a first line therapy for the treatment of metastatic prostate cancer. Since its introduction, point mutations have been identified, in patients and cell lines, which promote resistance to bicalutamide, including a well characterized mutation at codon 742 in the AR LBD.

Second Generation Antiandrogens

Enzalutamide (Table 2) was first described in 2009 as a second-generation antiandrogen with higher affinity for the AR than bicalutamide, and capable of retaining activity in the presence of increased AR expression, often seen in metastatic PCa. Enzalutamide also prevented nuclear translocation of the AR and impaired binding of the AR DNA binding domain to hormone response elements in androgen responsive genes (McEwan, 2013). Since its identification, enzalutamide has entered the clinic for therapeutic use in several developed countries. Despite its increased efficacy compared to bicalutamide, research has still unveiled mechanisms of resistance in patients, including an inactivating F868L mutation in the AR LBD (Lallous et al., 2016). Resistance is also conferred by the expression of AR splice variants lacking the LBD (Antonarakis et al., 2014). A long, non-coding RNA *Malat1* has also been shown to drive enzalutamide mediated selection of AR-v7 expression and downregulation of this splice variants can be achieved by siRNA and the degradation enhancer ASC-J9 (Wang et al., 2017).

The F868L mutation has also been shown to confer resistance to apalutamide (ARN-509, Table 2) which is currently in phase III clinical trials for castrate-resistant prostate cancer (Balbas et al., 2013). Although apalutamide was reported to have greater efficacy than enzalutamide in animal models of PCa, alongside absence of AR nuclear localisation or DNA binding, it remains to be seen how the drug will compare to enzalutamide in a large-scale trial.

Non-Competitive Antiandrogens

Unlike the LBD, the AR amino terminal domain is critical for receptor function and is structurally intrinsically disordered. Development of resistance to antiandrogens in prostate cancer, driven by mutated and splice variant isoforms of the AR which lack the LBD, provides a new opportunity for researchers to develop therapies that deviate from classical competitive inhibition.

The bisphenol A derivative EPI-001 (Table 2) was identified by preclinical screening of marine sponge extracts and shown to be capable of binding to and inhibiting the AR via an interaction in the amino terminal domain of the receptor, which is required for recruitment of co-regulatory proteins and proper receptor function (Andersen et al., 2010). EPI derivatives were capable of inhibiting the AR and reducing tumor burdens in animal models and entered phase I/II clinical trial as EPI-506 in 2016. Naphetenone B and Sinkotamides A–E are other marine compounds reported to mediate antiandrogen activity by binding to the AR amino terminal domain. However naphetenone B also has activity at the glucocorticoid receptor, and these small molecules remain the subject of preclinical research.

Selective Androgen Receptor Degradors (SARDs)

ASC-J9 (Table 2) was first described as an AR inhibitor in spinal-bulbar muscular atrophy (SBMA or Kennedy's disease). Unlike previously described antiandrogens, ASC-J9 is proposed to selectively enhance degradation of the AR by disrupting the interactions

between the AR and co-regulatory proteins such as ARA-70. This degradation is not dependent on the presence of testosterone, and ASC-J9 is capable of degrading wild-type AR in addition to the enzalutamide resistant F868L mutant receptor, and the splice variant AR-v7 (Wang et al., 2017). Several mechanisms have been proposed for ASC-J9's action in prostate, renal and bladder cancers, including: modulation of inflammatory cytokine signaling; inhibition of cancer stem cell proliferation; and modulation of hypoxia inducible factor and vascular endothelial growth factor signaling. ASC-J9 has been tested clinically as a topical therapy for acne (www.clinicaltrials.gov).

Galeterone (Table 2) has been shown to reduce AR expression by increasing degradation, reducing expression of both full length AR and AR-v7. Galeterone is also active against the T878A and F868L mutant ARs. Phase I and II clinical trials have been undertaken with galeterone, showing that the drug is well tolerated and has measureable effects on PSA levels. Further trials are ongoing (www.clinicaltrials.gov).

Natural products have also been identified as a potential source of SARDs, including piperlongumine, a naturally occurring alkaloid of the long pepper (*Piper longum*); berberine, an isoquinoline alkaloid from the *Berberis* genera; and isosilybin B, a *Silybum marianum* or "milk thistle" extract.

Rationally designed SARDs have also been developed preclinically. Based on the AR ligand arylthiohydantoin RU59063, SARD279, and SARD033 are linked to a hydrophobic adamantyl group which is effective at causing selective degradation of the target protein (Gustafson et al., 2015). Other steroid conjugates include PROTACS: proteolysis targeting chimeric molecules, in which an AR ligand is attached to a recognition element for ubiquitin-protein ligase, and specific and non-genetic inhibitor of apoptosis protein (IAP) dependent protein erasers, or SNIPERs, which recruit IAP ubiquitin ligases to the AR (Shibata et al., 2017).

Mutations in the Androgen Receptor Altering Ligand Binding Properties

Mutations in the AR LBD have been associated with failure of testosterone and DHT to act resulting in androgen insensitivity syndrome, which is a partial or complete failure of male development in XY individuals. Point mutations in the receptor can disrupt hormone binding affinity, increase dissociation rate or alter binding specificity (<http://androgendb.mcgill.ca/>).

Conversely, the failure of antagonists such as bicalutamide and enzalutamide is correlated with prostate cancer progression to a castrate resistant stage (<http://androgendb.mcgill.ca/>). The mutation of threonine 878, to alanine, found in the prostate cell line LNCaP, directly disrupts the binding to the C17 group and broadens the types of steroid that can be accommodated in the LBP and is associated with loss of antagonism by hydrox-flutamide. The mutation results in an altered positioning of Helix 12 switching the activity of the antiandrogen to an agonist. Mutation of tryptophan 742 to cysteine and phenylalanine 868 to leucine, also part of the LBP, have been associated with resistance to the antiandrogens bicalutamide and enzalutamide respectively (Lallous et al., 2016).

Conclusions

The activity of the full-length AR is finely regulated by the binding of agonists or antagonists to activate or blunt the receptor response. The binding of the natural hormones testosterone or DHT to the LBD causes local structural rearrangements, receptor dimerization and allosteric regulation of receptor function. These events can, to a greater or lesser extent, also be achieved through various synthetic agonists. Conversely, switching off AR activity with antagonists is important in the treatment of a range of hormone-dependent diseases from acne to cancer. However, the therapeutic use of agonists and antagonists of the receptor is not without difficulties and side-effects, which can limit the effectiveness of such treatments. There is therefore a continued need for research into the mechanisms underpinning tissue-selective androgen action and receptor expression. Such investigations will be fundamental to the development of new molecules to target AR signaling in a more tissue-specific manner and thereby increase the effectiveness of androgen replacement or ablation treatments.

Introduction

Aggression is one of the most important social behaviors. It is displayed by virtually all animals and serves a wide range of adaptive functions. Aggressive behaviors enable the acquisition and defense of limited valuable resources, such as mates, territories, shelters, and food. However, aggressive encounters are also a costly investment in terms of time, energy, predation risk, and physical injury. Animals evaluate the costs and benefits of competing for resources in search of maximal fitness payoffs to make the decision to fight or give up. In this way, aggressive behaviors mediate the establishment of dominance and subordination relationships among competitors that enable access to a given limited resource. In the context of choosing a mate, for example, the contenders evaluate strength and establish dominance in front of a potential mate. In solitary or territorial species, aggression implies exclusive use of a resource, but in gregarious species, aggression sets relations of dominance and establishes hierarchies. Consequently, aggressive interactions have a direct impact on the survival and reproductive success of individuals.

Historically, studies on aggression have focused on male–male competition. However, aggression is not exclusive to males and occurs not only during competition for a mate. Female–female contests, although less studied, are also seen in nature. Just like in males, preferential access to a resource is advantageous for females, which drives this behavior. Aggression has been defined in a variety of ways. Aggression has traditionally been defined as an overt behavior with the intention of inflicting physical damage upon another individual. Different classifications of aggressive interactions have been proposed, although they have only more recently been defined around the context in which they occur: 1- Territorial aggression; 2- Disputes over food; 3- Aggression to establish relationships of dominance; 4- Parental aggression; 5- Aggression for sexual competition; 6- Antipredator aggression; 7- Irritable aggression.

The neuroendocrine mechanisms of aggressive behavior are conserved in vertebrates and have been principally studied during the breeding season. These studies have focused on male–male interactions and on the role of gonadal steroid hormones, predominantly testosterone (T), as the primary factor regulating aggression. The objective of this article is to provide a brief overview of the endocrine mechanisms modulating aggressive behavior, describing the role of both gonadal and nongonadal steroids. In addition, we discuss the neural circuits that underlie aggression and the role of androgens in promoting aggressive behaviors in primates.

Endocrine Mechanisms of Aggression

Gonadal Steroids

Traditionally, blood-borne gonadal steroids have been the primary focus of neuroendocrine studies on aggression (**Fig. 1**). The potential role of androgens in aggressive behavior was first explored in roosters in the mid-19th century by Arnold Berthold. In his classic “ablate and replace” study, Berthold removed the testes of sexually immature male chickens and found that castrated male chickens, called capons, exhibited a decrease in the development of certain secondary sex characteristics, such as wattles and a prominent comb; and a decrease in male-typical behaviors, including aggression and mating behaviors. However, when testes were transplanted into capons, the capons exhibited normal behavioral and morphological development. Berthold also observed via dissection that the testes had developed additional vasculature following transplantation, suggesting that a blood-borne factor secreted by the testes is essential for proper behavioral, physiological, and morphological development in roosters. This compound, which Berthold termed “productive verhältnis der hoden,” is now known as the androgen T. Berthold’s experiment was the first to provide evidence that gonadal T regulates aggression in males.

Since the publication of Berthold’s work, numerous studies have provided evidence that circulating gonadal steroids, such as T and estradiol (E₂), promote aggression by binding directly to androgen receptors (AR) and estrogen receptors (ER) in the brain, modulating neural pathways relevant to aggressive behavior. Sex steroid secretion is particularly important in facilitating aggression during the breeding season, when aggressive behavior may be crucial to acquiring a mate and maintaining territorial boundaries. In seasonally-breeding vertebrates, the gonads grow before the breeding season and regress following the termination of breeding. Circulating sex steroid concentrations fluctuate alongside gonadal growth and regression, and high levels generally occur during the breeding season and basal or nondetectable levels occur during the nonbreeding season.

While gonadal steroid secretion is important in modulating aggressive behaviors, recent work indicates that these behaviors are not exclusively regulated by gonadal steroids. There is now strong evidence that the brain is capable of metabolizing circulating gonadal steroids and precursors (such as dehydroepiandrosterone, DHEA) and even synthesizing these steroids *de novo* from cholesterol (**Fig. 1**). Additional steroidal and nonsteroidal hormones play a role in modulating aggression, including glucocorticoids, a class of steroids known for their antiinflammatory and immunosuppressive effects.

Fig. 1 Pathways by which steroids could affect aggression. (A) Gonadal testosterone (T) acts directly on the brain; (B) gonadal T is converted locally to estradiol (E_2); (C) adrenal dehydroepiandrosterone (DHEA) is converted locally to T and/or E_2 ; (D) neurosteroids are produced locally de novo from cholesterol (CHOL) via conversion to pregnenolone (PREG), DHEA, androstenedione (AE), T, and E_2 , in the absence of gonadal and adrenal steroid production.

Nongonadal Steroids

DHEA is an inert androgen precursor that can be metabolized in tissues that express the appropriate steroidogenic enzymes. DHEA is secreted by the adrenal glands and can travel in the circulation as DHEA-S, the sulfated form of DHEA. Once DHEA has reached a target organ or tissue, it can bind with very low affinity to several different types of hormone receptors, including AR, ER, and glucocorticoid receptors. Alternatively, DHEA can be locally converted to active steroid hormones, such as T and E_2 , which can then bind with high affinity to AR and ER, respectively.

The role of DHEA in modulating aggressive behavior has mostly been studied in vertebrates that exhibit year-round aggression, particularly some birds and rodents. Both males and females of these species exhibit territorial aggression outside of the breeding season, despite the fact that the gonads are regressed and circulating androgen levels are low. In fact, the aggressive behaviors observed in nonbreeding some birds are qualitatively and quantitatively similar to those displayed during the breeding season, while Syrian and Siberian hamsters actually show increased aggression toward conspecifics when they are not in breeding condition. Interestingly, these animals also consistently display elevated plasma, gonadal, and adrenal DHEA levels, suggesting that the adrenals and gonads are secreting DHEA into the circulation during the nonbreeding season. Moreover, there is emerging evidence that nonbreeding birds and rodents can display locally elevated DHEA and androgen levels and increased AR and ER in brain regions associated with aggression. Thus, seasonally-breeding animals use two different neuroendocrine mechanisms to sustain year-round territorial aggression: breeding animals rely on circulating gonadal steroids to promote aggressive behaviors, whereas reproductively quiescent animals use circulating DHEA and DHEA synthesized de novo in the brain as an alternative source of androgens during the nonbreeding season.

Because seasonally-breeding vertebrates rely on an alternative mechanism to maintain aggression year-round, physiological indicators of season are critical in signaling animals to shift from one mechanism to another throughout the year. In particular, the hormone melatonin plays an essential role in initiating the physiological and endocrine changes necessary for this "seasonal switch." Melatonin is secreted by the pineal gland, a structure located between the cerebellum and cerebral cortical hemispheres of the brain. Melatonin secretion is high at night and low during the day; therefore, changes in day length, or photoperiod, result in changes in the pattern and duration of melatonin secretion. For example, some species of seasonally-breeding rodents, such as Siberian hamsters, breed during the summer, when there is a longer photoperiod than the winter. During the summer, the duration of melatonin secretion is short compared to the winter. Circulating melatonin binds to melatonin receptors on the gonads and adrenals, resulting in a decrease in gonadal steroid synthesis and an increase in adrenal DHEA synthesis (Fig. 2).

While the adaptive value of this alternative neuroendocrine mechanism of aggression is still being investigated, there are several potential benefits of utilizing DHEA as a source of androgens during the nonbreeding season. For example, maintaining high levels of aggression year-round may benefit individuals by allowing them to gain access to limited food resources and to defend their territories. Furthermore, the regulation of aggressive behaviors via this mechanism is far less energetically costly than sustaining high levels of circulating sex steroids. During the breeding season, a significant amount of energy is devoted to reproductive

Fig. 2 Theoretical model describing the relationships among melatonin (MEL) secretion, seasonal changes in serum testosterone (T) and dehydroepiandrosterone (DHEA) levels, and aggression in male Siberian hamsters. During the summer, long-day photoperiods (LD) result in a short duration of MEL secretion compared to the short-day photoperiods (SD) of the winter. During LD, T is secreted from the testes, whereas during SD, DHEA is secreted by the adrenal glands. Dotted lines and smaller font sizes symbolize less abundant levels of hormones than solid lines and larger font sizes. T can either directly bind to neural androgen receptors (AR) or can be locally converted to estradiol and bind to neural estrogen receptors (ER). Differences in AR and ER binding and/or abundance in the brain result in changes in aggression, and in hamsters, there is higher aggression during SD than LD.

physiology, such as maintaining the gonads, often at the expense of other physiological processes. Thus, by using an inert precursor (e.g., DHEA), which can be locally and quickly converted to androgens, an individual can exhibit year-round aggression without incurring the energetic costs of maintaining high gonadal steroid levels.

Neural Circuits of Aggression

The regulation of social behavior, such as aggression, depends on neural circuits, including the social behavior network (SBN). These well-studied neural circuits consist of reciprocally connected brain regions, or nodes, located in the forebrain, midbrain, and hindbrain. In mammals, the SBN consists of six nodes: the extended medial amygdala [the medial amygdala and the medial bed nucleus of stria terminalis (BnST)], the lateral septum (LS), the preoptic area (POA), the anterior hypothalamus, the ventromedial hypothalamus (VMH), and the periaqueductal gray. Each of these nodes regulates multiple forms of social behaviors, including sexual behavior, parental behavior, and aggressive behavior. Thus, this network works as a whole, where each region of the network responds to several social stimuli, rather than working independently in the regulation of distinct types of social behavior. In this way, the SBN receives and evaluates external stimuli, integrates them with internal physiological information, and produces an appropriate response with a distinctive circuit activity pattern, biasing behavior that is adaptive for a specific context. For example, across brain nodes, there is a particular pattern of neural activation for sexual behavior, and the same brain nodes show a different pattern of neural activation for aggressive behavior.

Social behavior emerged early in animal evolution, playing a key role in determining the survival and fitness of individuals. Therefore, its neural control is under strong evolutionary pressures. Neuroanatomical and functional studies that assessed the distribution, connectivity, and neurochemistry of the brain nodes of the SBN have found that the neural circuits that regulate social behavior are highly conserved across vertebrates and play similar roles in the regulation of these behaviors. Similarly, despite the diversity of social behaviors regulated by this network (i.e., aggression or paternal care), the neural circuits and hormones involved in modulating these behaviors have been highly conserved in all vertebrate lineages. Birds, reptiles, amphibians, and teleost fish all contain nodes of the SBN that are homologous with the mammalian counterparts described above and have similar activation patterns in similar social contexts. The conservation of these nodes enables comparative studies in different species to establish general principles among vertebrates.

More recent work suggests that a broader social decision-making (SDM) network regulates adaptive social behaviors in response to different context or stimuli. The SDM consists of both the classic SBN nodes and also the mesocorticolimbic reward system. The mesocorticolimbic reward system is composed of several interconnected nodes, including the ventral tegmental area (VTA) and

nucleus accumbens. The VTA contains dopamine-producing neurons that project to the nucleus accumbens and other forebrain regions. Signaling from these dopaminergic neurons regulates several different behaviors, including motivational aspects of motivation, preparatory behavior, and appetitive behavior. Additionally, this system is involved in positive reinforcement associated with stimuli, a fundamental aspect for the expression of appetitive-approach behaviors. The SDM network appeared early in evolution and is also highly conserved among vertebrates.

Every node of the SBN and SDM expresses sex steroid receptors, indicating that these brain regions are sex steroid-sensitive and that hormones play key roles in modulating the activity of these networks and regulating social behaviors. Sex steroids, such as androgens and estrogens, act on the central nervous system by binding to their intracellular receptors (e.g., AR and ER). Bound receptors act as transcription factors to regulate gene expression in brain cells. This genomic mechanism of action allows steroid hormones to modulate the activity of the different brain regions and act indirectly, but not deterministically, on the execution of a behavior. For instance, sex steroids can change a stimulus response threshold, such as the response threshold toward a competitor, but do not typically trigger aggression itself. The genomic effects of steroid hormones on the central nervous system require several hours or days to develop and produce persistent changes in physiology and behavior.

In addition, sex steroids can exert short-term (within 30 min) nongenomic effects, which are often mediated by plasma membrane receptors or by the allosteric modulation of neurotransmitter receptors. For example, ER, such as ER α and ER β , can be associated with the plasma membrane and rapidly regulate intracellular signaling pathways. Another membrane-associated ER is the G-protein-coupled estrogen receptor-1 (GPER-1), which is also present in the brain. Estrogens rapidly influence aggressive behaviors in birds and mammals via intracellular signaling in the SBN and SDM. These rapid effects are more prominent during short photoperiods in both mice and song sparrows. Interestingly, E₂ administration has been shown to rapidly (within 30 min) increase aggression exclusively during the nonbreeding season in both deer mice and song sparrows. These data suggest that steroids act via nongenomic mechanisms to maintain nonbreeding aggression in mammals and birds.

Furthermore, androgens and estrogens produced by the testes and ovaries are under neural influence via the hypothalamic-pituitary-gonadal axis, or HPG axis. Within the HPG axis, the hypothalamus integrates neuroendocrine input and environmental stimuli to regulate the release of gonadotropin-releasing hormone (GnRH). In turn, GnRH secretion stimulates the release of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) from the pituitary gland, which then stimulate gonadal secretion of sex steroids. Circulating sex steroids reach virtually every cell in the body, including cells in the central nervous system, where they can bind to sex steroid receptors and regulate cells in the SBN and SDM.

In addition, the brain itself is capable of locally synthesizing sex steroids. The brain possesses the necessary enzymes for steroidogenesis and can synthesize active sex steroids called neurosteroids, either from inert androgen precursors or de novo from cholesterol (Fig. 1). Neurosteroids can regulate behavior via actions on the SBN and SDM. For example, in male song sparrows, aromatase, the enzyme that converts androgens into estrogens, is critical for the expression of aggression in the breeding season, but also in the nonbreeding season when circulating sex steroids are nondetectable. Several brain regions, such as the POA, VMH, and BnST, contain elevated levels of aromatase year-round. In contrast, aromatase activity decreases in the nucleus taeniae, which is similar to the mammalian medial amygdala, during the molt, when song sparrows also show a decrease in aggressive behaviors. Similarly, the activity of brain 3 β -hydroxysteroid dehydrogenase/ Δ 5- Δ 4 isomerase (3 β -HSD), an enzyme that catalyzes the conversion of DHEA to an active androgen, changes with season and social context. In song sparrows, 3 β -HSD activity is higher during the nonbreeding season in multiple brain areas, and an aggressive social stimulus rapidly increases enzymatic activity in the brain. Together, these data provide evidence of neural steroidogenesis and suggest that local neurosteroid production occurs predominantly during the nonbreeding season.

Androgens and Primate Aggression

Aggression has been a central topic of human and nonhuman primate research for many years. Considerable research indicates the importance of environmental and social influences on the development and expression of primate aggressive behavior. Dominance is the most well-known social influence on aggression, and dominance hierarchies are a major organizing principle in many primate societies. Although the hormonal mechanisms of primate aggression have been studied, much less is known compared with rodents. Most recent studies on the neuroendocrine regulation of primate aggression measure androgens in feces or urine. While collection of such samples can be performed noninvasively, excreted levels frequently represent a fraction of plasma levels. In general, high rates of aggression are positively correlated with elevated androgen concentrations in nonhuman primates. This correlation is observed in seasonal changes in androgens and aggression, sex differences in aggression, and increased aggression at puberty.

Many primates reproduce seasonally and have provided information on correlations between androgens and aggression. Seasonality in testicular activity, with peak circulating T concentrations during the mating season, has been reported in many primates. Although exceptions exist, the majority of research suggests that androgens do not necessarily cause aggression in nonhuman primates. In Japanese macaques, seasonal increases in circulating androgens precede seasonal increases in aggression by several months, suggesting that these hormones do not affect aggression in a simple causal way. Further, experimental elevations of T do not reliably increase aggression. In rhesus monkeys, injections of human chorionic gonadotropin stimulated T production, but had no consistent effect on rates of aggression. Rather, increased circulating T levels were associated with an intensification of existing behavior, which did not disrupt group stability. In contrast, injections of T propionate increased aggression in dominant male long-tailed macaques (*M. fascicularis*), but increased submission in subordinates. When male marmosets (*Callithrix jacchus*) were castrated as neonates and tested as adults, they displayed high rates of aggression with female partners and low rates with

male partners. Moreover, the effects of neonatal castration on aggressive behavior were reversed by T treatment in adulthood. Several studies have found that castration of adult males has little effect on their aggressive behavior, suggesting that gonadal T is not required to maintain aggression in adults.

Some studies in nonhuman primates also suggest that aggressive behavior can be unrelated to fecal T levels, but related to adrenal androgens. Although the adrenal gland can secrete high levels of DHEA and DHEA-S, the role of adrenal DHEA and DHEA-S in primate aggression is largely unknown. One study assessed circulating DHEA-S levels in a population of wild baboons and found high DHEA-S concentrations in both male and female baboons, showing marked age-related decreases in both sexes. DHEA-S levels were not compared with aggressive behaviors, however.

Although the study of DHEA as a regulator of aggression in humans has received some limited experimental attention, much less is known about this mechanism compared to nonprimates. However, alterations in DHEA and DHEA-S have been implicated in a range of psychiatric disorders in humans. Circulating levels of DHEA-S are generally 1000-fold higher than levels of DHEA in humans. Studies from rodents and birds suggest that androgens, such as DHEA, may regulate aggression in situations where aggression seems otherwise T-independent. Adrenal DHEA appears to play a role in human aggression, as indicated by studies on "conduct disorder," typically defined as a collection of symptoms, including aggression directed toward people or animals, destruction of property, theft, and serious violations of rules. Prepubertal boys with conduct disorder were found to have higher levels of plasma DHEA-S, but not T, than normal control boys. Also, DHEA-S concentrations were correlated with the intensity of aggression as rated by parents and teachers. In another study, plasma DHEA-S concentrations were found to be higher in boys with conduct disorder than in boys with attention-deficit/hyperactivity disorder (ADHD) or normal controls. Recent research has examined circulating levels of cortisol, DHEA and DHEA-S in delinquent adolescent boys diagnosed with conduct disorder compared with healthy controls. Hormone levels were correlated with aggression as determined by the Child Behavior Checklist and the Overt Aggression Scale. Delinquent boys had higher DHEA-S levels than control boys, but did not show any differences in either DHEA or cortisol. Collectively, these data suggest a relationship between DHEA-S and aggression, at least in male adolescents diagnosed with clinically-relevant psychiatric conditions.

Adrenal androgen precursors may also contribute to the regulation of aggression in human females. Adolescent and adult females with congenital adrenal hyperplasia who were exposed to high levels of adrenal androgen precursors in the prenatal and early postnatal periods were found to have greater self-reported aggression ratings than were control females. More recently, adrenal androgen precursor levels have been determined in adolescent girls diagnosed with conduct disorder. Specifically, blood samples were drawn from adolescent girls with either conduct disorder or no psychiatric disorder, and samples were assessed for DHEA, DHEA-S, cortisol, and gonadal androgens and estrogens. Girls with conduct disorder scored higher on a clinical aggression scale and demonstrated significantly lower cortisol to DHEA ratios, but did not differ from control girls on any other hormone measurement. Furthermore, girls diagnosed with aggressive conduct disorder had lower cortisol to DHEA ratios than those with nonaggressive conduct disorder.

In addition to regulating aggression in adolescents, DHEA also modulates aggressive behaviors in adults. In a study of alcohol withdrawal, serum levels of DHEA-S and cortisol, as well as DHEA-S response to treatment with an exogenous steroid, dexamethasone, were determined in adult alcohol-dependent or healthy control males. Alcohol-dependent subjects displayed reduced basal and dexamethasone-induced levels of DHEA-S compared with control subjects in late alcohol withdrawal. When alcohol-dependent subjects were separated into high and low aggression groups, lower basal DHEA-S levels were seen only during early alcohol withdrawal in high aggression individuals, whereas DHEA was lower only during late withdrawal in low aggression individuals relative to control subjects. In contrast, dexamethasone-induced decreases in DHEA-S were observed during both early and late alcohol withdrawal, whereas lower DHEA levels were only seen during early withdrawal. While the meaning of these results is not entirely clear, these data suggest an important link between DHEA and aggressive behavior, at least under conditions of drug withdrawal. Whether a link between DHEA, DHEA-S and aggressive behavior exists in healthy adult and adolescent males and females remains to be determined. Regardless, it is clear that considerably more research on DHEA and human aggression is needed.

Conclusions

Aggression is displayed by virtually all organisms and allows males and females to compete for access to limited resources. Many studies have examined the endocrine and neural regulation of aggression, and these studies highlight the importance of steroid hormones, such as testosterone, and brain circuits, such as the social behavior network. Aggression occurs in a wide variety of physiological and environmental contexts, and the neuroendocrine regulation of aggression varies across contexts as well. For example, in the breeding season, gonadal sex steroids play important roles in the modulation of aggressive behavior, but in the nonbreeding season, neurally-synthesized sex steroids are critical. Furthermore, sex steroids affect aggressive behavior via both genomic and nongenomic mechanisms, and the balance between these two mechanisms of action depends on the physiological and environmental contexts. Despite the variability of aggressive behaviors across species, the relevant neural circuits and neuroendocrine mechanisms are generally well conserved. Therefore, comparative studies in different vertebrate taxa can shed light on common mechanisms and establish general principles in the control of aggression.

MALE REPRODUCTIVE TRACT

Male Reproductive Tract: Development Overview

Diya B Joseph and Chad M Vezina, University of Wisconsin-Madison, Madison, WI, United States

Introduction

Human male reproductive tract development is described in this chapter. The male reproductive tract consists of organs involved in the storage, maintenance and transportation of male reproductive cells. The major structures of the male reproductive tract originate from the endoderm-derived cloaca and the mesoderm-derived Wolffian duct. Male reproductive tract and urinary system development are closely linked and together their structures comprise the urogenital system. All human developmental ages mentioned in this chapter are counted from the day of fertilization.

Developmental Origins of the Male Reproductive Tract

Gastrulation gives rise to three germ layers: the endoderm, ectoderm and mesoderm. Male reproductive tract development begins early in gestation and involves cells from all three germ layers (Fig. 1). The cloaca is a transient pouch-like structure at the terminal

Fig. 1 Germ cell layer of origin of male reproductive tract structures. (A) Cross sectional view of a gastrulated embryo showing the three germ layers: endoderm (white), mesoderm (light gray) and ectoderm (dark gray). (B) Sagittal view of the male reproductive tract in a week 5 embryo during the bi-potential stage. (C) Sagittal view of the male reproductive tract in a week 10 embryo after the onset of sexual differentiation. Structures of the reproductive tract are colored according to germ layer of origin.

portion of the endoderm-derived hindgut in the early embryo. The cloaca (Latin for “sewer”) differentiates into the urogenital sinus, bladder, urethra and prostate in males. Paired epithelial Wolffian ducts derive from the mesoderm and insert into the cloaca. Testicular factors including testosterone masculinize male reproductive structures and drive cellular differentiation within them. The Wolffian duct gives rise to the epididymis, vas deferens, seminal vesicle and ejaculatory duct. In the mature adult, sperm from the testes are transported through the epididymis, vas deferens and ejaculatory duct to the urethra. At the urethra, the seminal vesicle and prostate contribute secretions to the ejaculate that promote sperm health. The urethra is the conduit for deposition of sperm during reproduction (Moore and Persaud, 2003).

Urogenital Sinus, Urethra, and Prostate

Growth and re-positioning of mesenchymal tissue divides the cloaca into the urogenital sinus ventrally and the anorectal sinus dorsally by week 7 of gestation.

Urogenital sinus

The ventral portion of the cloaca gives rise to the urogenital sinus (UGS). The UGS is a transient structure comprised of a simple epithelial tube featuring a balloon-shaped central cavity (Fig. 1). Paired Wolffian ducts insert into the UGS around week 4 of gestation. The UGS is divided into three parts:

- The cranial or upper part of the UGS differentiates into the urinary bladder.
- The middle or pelvic portion develops into the pelvic urethra and prostate.
- The caudal or lower part develops into the phallic urethra.

Urethra

The urethra develops from the middle and caudal regions of the UGS. The pelvic urethra extends from the bladder to the body wall. The phallic urethra extends from the body wall to the tip of the external genitalia. Urethral glands (Littre’s glands) and bulbourethral glands (Cowper’s glands) emerge as urethral outgrowths around week 12 of gestation.

Lineage tracing studies following the fate of endodermal cells within the developing urogenital tract show that the entire urethral epithelium derives from endoderm (Seifert et al., 2008). The developing urethra forms a stratified epithelium comprised of basal, intermediate, and superficial layers. Epithelial–mesenchymal interactions are crucial for urethral morphogenesis. Sonic hedgehog (SHH) peptide is secreted from epithelium and activates GLI transcription factors in nearby mesenchyme. GLI transcription factors drive bone morphogenetic protein 4 (BMP4) transcription and mesenchymal differentiation. Molecular mapping studies in the mouse embryo reveal a multilayered pelvic urethral mesenchyme consisting of lamina propria, muscularis mucosa, submucosa, and muscularis propria (Abler et al., 2011). Male urethra morphogenesis is guided by androgens, principally by androgen-induced signals from the male urethral mesenchyme that drive urethral epithelium differentiation and remodeling.

Prostate

The prostate is a male accessory sex gland positioned at the base of the bladder and surrounding the pelvic urethra. Prostate secretions contribute to the ejaculate and promote sperm health. Prostate ductal development initiates in utero as solid epithelial buds deriving from UGS epithelium. The epithelial buds elongate, branch, and canalize to form a complex ductal system draining into the urethral lumen. Most studies on early prostate development have been carried out in rodents. The early development program of prostate budding is remarkably conserved between rodents and humans, even though their prostates differ anatomically at sexual maturity.

In the human fetus, prostate development occurs in response to testosterone production by testicular Leydig cells around week 7 of gestation. Testosterone acts on androgen receptor (AR)-expressing UGS mesenchymal cells. AR activation increases the abundance of UGS mesenchymal steroid 5 alpha reductase type 2 (SRD5A2). SRD5A2 converts testosterone to the more potent dihydrotestosterone (DHT). DHT binding to AR amplifies androgen signaling in the UGS mesenchyme, which evokes paracrine signaling mechanisms that instruct UGS epithelium to form prostatic buds. Prostate bud outgrowth begins around week 10 of gestation and continues until week 24.

Studies in mice have shown that prostatic bud number and location are precisely controlled. The Nk-3 transcription factor locus-1 (NKX3-1) is the earliest marker of prostate specified UGS epithelial cells. Although prostatic bud formation cannot occur in the absence testosterone, several other factors including SHH, SOX9, HOXB13, and WNT5A are also required for prostatic bud formation and subsequent prostate ductal development.

Prostate formation is dependent on complex epithelial–mesenchymal interactions. Tissue recombination experiments have shown that androgen signaling deriving from UGS mesenchyme not UGS epithelium directs prostate bud formation. However, epithelial AR is required for prostate epithelial cell differentiation and secretory protein production. UGS mesenchyme is organized into distinct zones, and some zones serve as signaling centers to guide prostate morphogenesis. UGS mesenchymal condensations (mesenchymal pads) lie on the UGS periphery, are characterized by *FGF10* mRNA expression, and guide directional outgrowth of prostatic buds (Thomson and Cunha, 1999). Epigenetic mechanisms including DNA methylation and histone acetylation regulate expression of key genes involved in prostate development. DNA methylation controls E-cadherin (CDH1) and AR abundance,

which in turn control prostate bud elongation and timing of bud formation respectively (Keil et al., 2014a,b). Histone acetylation controls BMP2 expression to regulate prostatic ductal branching (Keil et al., 2015).

In later stages, the prostate undergoes branching, canalization and differentiation to form a pseudo-stratified epithelium consisting of basal cells, secretory luminal cells and rare neuroendocrine cells. The prostate increases in size following an upsurge in testosterone production during puberty. The study of early prostate development is receiving renewed interest as the reawakening of embryonic processes has been implicated in the pathogenesis of prostate cancer and benign prostatic hyperplasia.

Rete Testis, Epididymis, Vas Deferens, Seminal Vesicle

The intermediate mesoderm lies between paraxial and lateral plate mesoderm of the fetus and gives rise to ductal structures of the urogenital system. Crests of intermediate mesoderm called urogenital ridges form near the midline and along the cranio-caudal body axis. Early in week 4 of gestation, a non-functional, transient excretory organ called the pronephros develops within the urogenital ridge at the position of the thorax. The rudimentary tubular structures of the pronephros feed into the pronephric duct, which joins the cloaca at approximately week 4 of gestation. The pronephric duct is formed by mesenchymal to epithelial transition of intermediate mesoderm. The pronephros undergoes degeneration through an apoptotic program. The mesonephros forms caudal to the degenerating pronephros late in week 4 of gestation. The mesonephros contains glomeruli and mesonephric tubules that function as temporary kidneys until week 10 of gestation, when the metanephros permanently assumes kidney function. The mesonephric tubules open into mesonephric ducts (also known as Wolffian ducts) which drain into the cloaca. The mesonephros degenerates in the cranial to caudal direction around week 8, leaving a few residual tubules that will give rise to efferent ductules of the testes (Rao and Burnett, 2013).

The Wolffian ducts are precursors for ductal structures of the male reproductive and urinary tracts. The ureteric bud emerges as a Wolffian duct outgrowth near its insertion into the cloaca (Fig. 1). The ureteric bud undergoes branching and differentiation within a specialized mesenchyme called the metanephric blastema to form the metanephros or permanent kidneys. The ureteric bud is also the precursor for the ureters, which connect the kidneys to the bladder. The caudal portion of the Wolffian duct between the ureteric bud and the insertion site into the UGS is called the common nephric duct. Common nephric duct apoptosis positions the ureters at their final insertion site within the bladder, spatially separating the ureteral and Wolffian duct openings to the lower urinary tract. Ureter separation from the Wolffian duct is completed by week 7 of gestation. Paired box 2 (PAX2) expression marks the intermediate mesoderm early after gastrulation. Lineage tracing studies show that the PAX2 expressing intermediate mesoderm gives rise to Wolffian ducts, the ureteric bud and the metanephric blastema (Bouchard et al., 2002).

During the ambisexual stage, two sets of paired genital ducts are present in male and female embryos. The paramesonephric or Müllerian ducts extend in the craniocaudal direction and lie lateral to the Wolffian ducts. Müllerian duct formation occurs between week 6 and 7 of gestation. Lineage tracing studies in chick and mouse models demonstrate that Müllerian ducts develop from the coelomic epithelial layer, which derives from lateral plate mesoderm. Although Wolffian ducts lie in close apposition to and stimulate Müllerian duct formation, the Wolffian ducts do not contribute epithelial cells to the Müllerian ducts (Guioli et al., 2007; Orvis and Behringer, 2007).

Sexual differentiation of the male reproductive tract begins around week 7 of gestation. Müllerian inhibiting substance (MIS) produced by Sertoli cells and testosterone produced by the interstitial Leydig cells of the fetal testis act on the reproductive tract to induce male differentiation. MIS is a glycoprotein of the TGF- β family of growth factors which causes irreversible regression of the Müllerian ducts in males. Testicular MIS production commences by week 8 of gestation and Müllerian duct regression occurs between weeks 8 and 10. The prostatic utricle near the UGS and the appendix testis near the male gonads are Müllerian duct remnants in males. Female reproductive structures including the uterus, vagina and oviducts form in the absence of MIS. Testosterone-mediated AR activation supports Wolffian duct survival in males. Reproductive tract structures derived from the Wolffian ducts are formed between week 9 and 13 of gestation. Regional expression of homeobox (HOX) genes drives segmental differentiation of the Wolffian duct into the epididymis, vas deferens and seminal vesicle. The Wolffian ducts regress in females due to insufficient testosterone to support cell survival (Rao and Burnett, 2013).

Rete testis

After the mesonephros undergoes regression, the remaining mesonephric tubules form the efferent ductules. The seminiferous tubules, which contain sperm cells, are connected to the efferent ductules by a maze-like network of interconnecting tubes called the rete testis. The ciliated cells lining the rete testis guide sperm into the efferent ductules.

Epididymis

The efferent ductules, which receive sperm from the testis, drain into the epididymis. The epididymis is a convoluted series of tubules that derives from the portion of the Wolffian duct adjacent to the testis. The epididymis stores and transports sperm.

Vas deferens

The medial Wolffian duct segment forms the vas deferens. Androgens drive Wolffian duct differentiation into the vas deferens around week 12 of gestation. Smooth muscle surrounding the vas deferens contracts during ejaculation to propel sperm from the epididymis to the urethra.

Seminal vesicle

The seminal vesicles develop as lateral outgrowths from the caudal Wolffian duct segment. The seminal vesicles form around week 10 of gestation, after the onset of testosterone synthesis by the fetal testis. Seminal vesicles contribute secretions to the ejaculate. The most caudal Wolffian duct portion, positioned between the seminal vesicle and the urethra, is called the ejaculatory duct. Ejaculatory ducts drain the contents of the seminal vesicle and vas deferens into the urethra.

External Genitalia

Internal fertilization requires specialized male and female external reproductive organs. Lateral plate mesoderm, endoderm, and surface ectoderm cells contribute to the external genitalia. The initial phase of external genitalia development is essentially the same in males and females. In the later phase, androgens drive masculinization of the external genitalia in males (Blaschko et al., 2012; Yamada et al., 2003).

Early phase: Formation of ambisexual external genitalia

The early phase of external genitalia development, which occurs between 4 and 7 weeks of gestation, is essentially the same in males and females. This phase occurs independently of androgen action as it happens before the onset of testicular testosterone production. The cloacal membrane, formed by direct contact of the endoderm and surface ectoderm, is intact at 4 weeks of gestation. Proliferating lateral plate mesenchymal cells form paired lateral swellings above the cloacal membrane. These swellings fuse at the midline to form the genital tubercle. The genital tubercle is a bi-potential structure which is the precursor of the penis in males and clitoris in females. Paired mesenchymal swellings called urogenital folds and labio-scrotal swellings form on either side of the cloacal membrane. After cloacal septation around week 7, the cloacal membrane becomes the urogenital membrane ventrally and the anal membrane dorsally. The cloacal membrane ruptures at two sites to form the urethral orifice and the anal opening. The urogenital membrane is bounded by urogenital folds and lies within a temporary indentation on the ventral genital tubercle surface called the urethral groove. The urethral groove is lined by a solid cord of endodermal cells comprising the urethral plate epithelium. The urethral plate epithelium is the region of the phallic urethra distal to the UGS.

Studies in mice have shown that early patterning of the genital tubercle does not depend on androgens but does require Sonic hedgehog (SHH) signaling. Mice harboring inactivating mutations in the SHH gene fail to form external genitalia. SHH signaling from the urethral plate epithelium coordinates cell movements during external genitalia development (Perriton et al., 2002).

Later phase: Sexual differentiation of the external genitalia

Male testicular androgens induce genital tubercle differentiation into the penis. In females, the genital tubercle fails to elongate and forms the clitoris in the absence of androgens. Testosterone synthesis begins by week 7 and maximal concentrations in the fetus are achieved between weeks 10 and 15 of gestation. Early signs of sexual differentiation in the external genitalia can be detected by week 9 and complete differentiation is achieved by weeks 12–13.

The steroid hormone dihydrotestosterone (DHT) masculinizes the external genitalia. Testosterone is converted to DHT by the action of steroid metabolizing enzymes like SRD5A2 which are expressed in genital tubercle mesenchymal cells. DHT initiates androgen signaling in androgen receptor expressing mesenchymal cells. Interactions between androgen activated mesenchyme and urethral plate epithelium initiate male external genitalia differentiation.

Androgen exposure elongates the genital tubercle into the penis. Early in sexual differentiation, the proximal phallic urethra is a closed hollow tube but the distal portion comprising the urethral plate epithelium remains a solid mass of cells. The urogenital folds lining the penile ventral surface guide midline fusion of the urethral plate, forming a hollow urethral tube that extends the whole length of the penis. The fusion of urogenital folds occurs in a proximal to distal direction, positioning the urethral orifice at the tip of the penis. Hypospadias, a common birth defect, occur from defective fusion of urogenital folds. Specialized mesenchyme induces the differentiation of the distal urethral into a stratified squamous epithelium. The labio-scrotal swellings fuse in the midline to form the scrotum. The skin covering the developing penis is derived from surface ectoderm. Specialized structures of the penis, the corpus cavernosa and the corpus spongiosum, derive from the proliferation and differentiation of mesoderm derived cells.

The Genitourinary Development Molecular Anatomy Project (GUDMAP) website provides curated information on reproductive tract anatomy, histology, mRNA and protein expression over developmental time (www.gudmap.org).

Signaling Pathways in Male Reproductive Tract Development

Studies in rodents have greatly advanced our knowledge of signaling pathways involved in male reproductive tract development. Table 1 provides a parallel chronology of the major events in male reproductive tract development in human and mouse.

Sonic Hedgehog Signaling

Sonic hedgehog (SHH) peptide is a developmental morphogen secreted by epithelial cells. The secreted SHH peptide relieves the repression of smoothened (SMO) by binding to its inhibitor patched (PTC1). SMO activation initiates transcription of GLI transcription factors which are involved in several developmental and morphogenetic processes. SHH is expressed in

Table 1 Chronology of male reproductive tract development in human and mouse

Human	Internal reproductive tract	External genitalia	Mouse
Week 3	Gastrulation; cloacal membrane forms		E6-E6.5
Week 4	Nephrogenic cord forms pronephros forms cloaca develops from hindgut mesonephros forms Wolffian duct fuses with cloaca (day 26)	Genital tubercle forms	E8.5 E9 E9.5 E9.5–E11.5 E9.5 E11–E11.5
Week 5	Ureteric bud forms (day 28) Cloacal septation begins Common nephric duct apoptosis		E10.5–E11.5 E10.5 E11–E12
Week 6	Müllerian duct forms	Urogenital and labio-scrotal folds form	E12–E13 E14
Week 7	Cloacal septation complete Ureters join bladder Onset of testosterone synthesis	Cloacal membrane rupture	E13–E13.5 E13–E14 E13–E13.5
Week 8	Müllerian ducts reach UGS		E13.5
<i>Onset of sexual dimorphism</i>			
Week 9	Müllerian duct degeneration Wolffian duct differentiation		E16.5 E16.5–P1
Week 10	Müllerian duct degeneration complete Seminal vesicle forms Prostate forms Wolffian duct differentiation		E16.5 E16.5 E16.5–E18.5 E16.5–P1
Week 11	Wolffian duct differentiation		E16.5–P1
Week 12	Wolffian duct differentiation		E16.5–P1
Week 13		Urethral tube closure	E16.5
2nd Trimester		Growth of external genitalia Inguinal descent (week 23)	E15.5–P1 E15.5–E17.5
3rd Trimester		Growth of external genitalia Scrotal descent (weeks 24–34)	E15.5–P1 E17.5–P20

Provides a parallel chronology of male internal reproductive tract and external genitalia development in the human and mouse. Developmental age in humans is depicted here in weeks from the time of fertilization. Developmental age in the mouse embryo is depicted as days (E) from the time of fertilization.

hindgut-derived structures including the cloacal epithelium, where it patterns the surrounding mesenchyme. SHH induces mesenchymal GLI2, which regulates epithelial and mesenchymal proliferation and apoptosis during cloacal development. SHH regulates cloacal septation by promoting proliferation of mesenchymal cells in the urorectal septum (Seifert et al., 2009). SHH signaling is required for prostate formation and external genitalia development. Treatment with SHH inhibitors impairs prostate ductal growth and morphogenesis (Podlasek et al., 1999). SHH knockout mice show a complete absence of external genitalia (Haraguchi et al., 2001).

WNT-Beta Catenin Signaling

WNT ligand binding to cell surface Frizzled receptors stabilizes and activates the transcription factor beta-catenin. WNT signaling is involved in several aspects of urogenital development including the septation of the cloaca into the urogenital and anorectal sinuses. Disruption of WNT signaling results in rectourethral fistulas (abnormal connection between the urethra and rectum). Epithelial beta-catenin is also required for prostate development and growth (Mehta et al., 2013). The WNT-beta catenin pathway acts downstream of SHH signaling to regulate external genitalia development (Miyagawa et al., 2009).

Bone Morphogenetic Proteins

Bone morphogenetic proteins (BMPs) are growth factors belonging to the TGF-beta superfamily. BMPs bind to serine threonine kinase receptors and initiate intracellular signaling through SMAD proteins. BMP7 expression in the urorectal septum is required for cloacal septation. In addition, BMP7 expression maintains proliferation and cell survival in the cloacal epithelium (Xu et al., 2012). Expression of BMP7 in the UGS mesenchyme restricts prostate ductal budding and prevents excessive branching of elongating ducts (Grishina et al., 2005).

Fibroblast Growth Factors

Fibroblast growth factors are a family of secreted growth factors that signal through tyrosine kinase fibroblast growth factor receptors to regulate proliferation, differentiation and morphogenesis during embryonic development. FGF signaling is required for cell survival during the early stages of genital tubercle outgrowth. FGF signaling in the ectoderm is required for urethral tube formation. Deletion of FGF10 or its receptor FGFR2 results in severe hypospadias (Harada et al., 2015). FGFR2, a critical regulator of prostate development, is required for branching and growth of prostate buds. FGF10 is a paracrine mediator of epithelial to mesenchymal signaling during prostate bud formation. FGF10 knockout mice fail to form prostate, seminal vesicle, bulbourethral glands and caudal vas deferens (Thomson and Cunha, 1999).

PAX Genes

Paired box (PAX) genes are tissue specific transcription factors that determine lineage specification in the early embryo. PAX2 and PAX8 are required for Wolffian duct formation from the intermediate mesoderm. In PAX2 and PAX8 double mutant mice, the intermediate mesoderm fails to undergo the mesenchymal to epithelial transition required for Wolffian duct formation (Bouchard et al., 2002). GATA3, a downstream effector of PAX2, regulates Wolffian duct growth and caudal extension which is required for fusion with the cloaca and formation of definitive kidneys (Grote et al., 2006).

EPH Receptors/Ephrins

EPH receptors are a family of receptor tyrosine kinases with plasma membrane bound ligands called ephrins. EPH receptor/ephrins are involved in the maintenance of cell–cell adhesion and communication between similar or different cell types during developmental processes. The ephrin receptors EPHA4 and EPHA7 are expressed in the mesenchyme surrounding the cloaca and Wolffian duct where they mediate Wolffian duct fusion with the cloaca (Weiss et al., 2014). Signaling from EPHA4 and EPHB2 is required for apoptosis of the common nephric duct for proper separation of ureters from Wolffian ducts (Peuckert et al., 2016). EphrinB1 expressed by prostatic mesenchyme regulates prostate growth and branching (Ashley et al., 2010).

Vitamin A/Retinoic Acid Signaling

Retinoic acid, a derivative of vitamin A (retinol), binds to nuclear retinoic acid receptors to activate transcriptional programs for differentiation and organogenesis. The spatial expression of retinaldehyde dehydrogenases, which convert retinaldehyde to retinol, is tightly regulated in a tissue specific manner. Apoptosis induced by retinoic acid signaling is required for ureter separation from the Wolffian duct and proper positioning in the bladder (Batourina et al., 2005). Retinoic acid is a powerful inducer of prostate budding (Vezina et al., 2008a). Retinoic acid signaling regulates external genitalia formation by maintaining SHH and BMP4 expression in the genital tubercle (Liu et al., 2012).

Müllerian Inhibiting Substance

Müllerian inhibiting substance (MIS) or anti-Müllerian hormone (AMH) is a gonadal hormone secreted by Sertoli cells of the developing testis. The secreted glycoprotein MIS belongs to the TGF-beta family of transcription factors. MIS acts through AMH Type II receptors expressed by Müllerian duct mesenchyme to initiate apoptosis and degeneration of the Müllerian duct (Behringer, 1995; Abler et al., 2011).

Androgens, INSL3

Testosterone synthesis initiates from fetal Leydig cells during week 7 of gestation. Testosterone is converted to the more potent dihydrotestosterone (DHT) by the enzyme SRD5A2. DHT acts on AR expressing cells to initiate androgen-dependent transcriptional programs. DHT regulates prostate and seminal vesicle formation, external genitalia masculinization and formation of the vas deferens and epididymis. The Leydig cell specific insulin-like peptide INSL3 binds to relaxin/insulin like family peptide receptor 2 (RXFP2) to promote testicular descent into the scrotum (Barsoum and Yao, 2006).

Endocrine Disruptors

Environmental toxins with the capability of interfering with endocrine signaling are known as endocrine disruptors (Prusinski et al., 2016). In utero exposure to endocrine disruptors adversely affects hormone-dependent development and increases risk of adulthood disease. Maternal exposure to low doses of Bisphenol A, an estrogenic compound found in plastics, has been shown to increase prostate size in rodent models (Gupta, 2000; Dolinoy et al., 2007). Early exposure to Bisphenol A can also increase the risk of prostate cancer in rodent models of estrogen-induced carcinogenesis by inducing long-term changes to the DNA methylome (Cheong et al., 2016). The anti-androgenic endocrine disruptor vinclozolin found in fungicides, can induce

hypospadias in mice (Buckley et al., 2006). In utero exposure to persistent environmental pollutants called 2,3,7,8 tetrachlorodibenzo-*p*-dioxin impairs reproductive function of male and female rodents (Gray and Ostby, 1995; Bjerke and Peterson, 1994). In utero dioxin exposure disrupts mouse prostate formation (Vezina et al., 2008b) and sensitizes mice to hormone-mediated urinary dysfunction (Ricke et al., 2016).

Congenital Anomalies of the Male Reproductive Tract

Congenital anomalies of the male reproductive tract can reduce fertility. Hypospadias are the most common congenital anomaly of the male reproductive tract, with an occurrence of 1 in 250 live male births. Hypospadias occur when the urethral opening is not at the tip of the penis, but instead on the ventral surface or scrotal region. Defects in urethral tube closure result in hypospadias (Baskin and Ebbes, 2006). Genetic, endocrine and environmental factors have been implicated in the occurrence of hypospadias. Epispadias, which occur when the urethral opening is on the dorsal surface of the penis, is a much rarer condition (affecting 1 in 117,000 males) (Gearhart and Jeffs, 1992). Unlike hypospadias, epispadias result from defects in the cloacal membrane (Suzuki et al., 2017). Another congenital anomaly called chordee is associated with increased curvature of the penis. A congenital condition called posterior urethral valves is associated with the occurrence of flaps of urethral tissue that obstruct urine flow and impair reproductive function (Agarwal, 1999).

Persistent Müllerian duct syndrome is a rare anomaly of the reproductive tract in which Müllerian duct derivatives (uterus and oviduct) persist in males. The persistence of Müllerian duct derivatives can be due to insufficient production of Müllerian inhibiting substance (MIS) or insensitivity of the Müllerian duct to MIS (Elias-Assad et al., 2016).

Congenital anomalies of Wolffian duct derivatives include ectopic insertion of the ureter into the urethra, seminal vesicle, ejaculatory duct or vas deferens. Ectopic ureters are a result of abnormal ureteric bud formation and abnormal separation from the Wolffian duct during kidney development. Ectopic ureter insertion into the seminal vesicle results in the development of congenital seminal vesicle cysts. Seminal vesicle anomalies on their own do not contribute to male infertility. However, these defects are often observed with other Wolffian duct defects that affect fertility (Kroovand and Perlmutter, 1981).

Defects in vas deferens development are a major cause of male infertility. Congenital bilateral absence of the vas deferens results in male infertility from obstructive azoospermia (lack of sperm in semen). This condition is highly prevalent in males who have abnormal mucus production from mutations in the cystic fibrosis transmembrane conductance regulator (CFTR) gene. Abnormal mucus production in affected individuals results in obstruction and destruction of the vas deferens, leading to infertility in later life (Stuhrmann and Dork, 2000). Other congenital anomalies of Wolffian duct derivatives include agenesis of the epididymis, epididymal cysts with loss of continuity, agenesis of the seminal vesicle and agenesis of the ejaculatory duct.

Glossary

Cryptorchidism Failure of one or both testes to descend into the scrotum.

Epididymis An elongated cord-like structure along the posterior border of the testis; its coiled duct provides for storage, transit, and maturation of spermatozoa and is continuous with the vas deferens (ductus deferens).

E2f4/E2f5 Is a member of the E2F family of transcription factors that contain a series of conserved domains including a DNA binding domain, a dimerization domain, a transactivation domain, and a tumor suppressor protein associated domain embedded within the transactivation domain.

Emx2 Empty spiracles homeobox 2 gene, is a transcription factor.

Foxc1/Foxd1 Forkhead box gene, is a transcription factor.

Gata3 GATA-binding factor 3, transcription factor 3 that binds to the DNA sequence "GATA."

Lim1 Transcription factor that binds to the LIM domain, a cysteine-rich zinc binding domain.

Mesoderm Layer of cell within the developing embryo between the ectoderm and endoderm. Divides into: (1) Paraxial mesoderm that gives rise to bone, cartilage and dermis. (2) Intermediate mesoderm that gives rise to the reproductive tract, lower urinary tract and the kidney. (3) Lateral plate mesoderm that gives rise to adipose, blood, endothelium, heart, smooth muscle, and spleen.

Mesonephric duct The duct of the mesonephros that persists in the male as the duct system leaving the testis including the epididymis, vas deferens, seminal vesicle, and ejaculatory duct.

Pax2 Paired-box containing gene, is a transcription factor.

Six1 Sineoculis homeobox homolog 1, is a transcription factor.

Testosterone Male sex hormone produced by the Leydig cells within the testis responsible for maintaining male secondary sex characteristics.

Transcription factor Proteins involved in the process of transcribing DNA into messenger RNA by binding to a specific DNA sequence.

Wolffian duct Eponym for the mesonephric duct. So named after Caspar Friedrich Wolff, who described the ducts in chick embryos.

Wt-1 Wilms tumor-1 gene, is a transcription factor.

Migration of Wolffian Duct Cells and the Formation of the Duct

During development the embryonic mesoderm splits into three divisions, the paraxial mesoderm, the intermediate mesoderm, and the lateral plate mesoderm. The mesonephros, from which the Wolffian and Müllerian ducts are derived, is formed from the intermediate mesoderm. The mechanism(s) by which the Wolffian duct begins at the rostral end of the embryo and then elongates to join the cloaca, the primitive bladder, is/are not well known. However, studies using the chick embryo have shown that once cells have undergone specification in the rostral end of the embryo, they migrate toward the cloaca under the influence of a gradient of fibroblast growth factor 8 (FGF8) and its signaling transduction pathways ([Atsuta and Takahashi, 2015](#)). So long as the cells are kept surrounded by high concentrations of FGFs, they maintain a migratory mesenchymal-like phenotype. The cells that are more distal, and therefore removed from the high concentrations of FGF8 undergo a mesenchymal-epithelial transition and form a lumen. The manner by which the cells undergo specification at the beginning of this event is not known. Several transcription factors are also required for Wolffian duct formation and maintenance including *Gata3*, *Lim1*, *Pax2*, *Wt-1*, *Six1*, *Emx2*, and *Foxc1/Foxd1* (see reviews by [Murashima et al., 2015b](#); [McMahon, 2016](#)). Null mutations of each of these genes results in varying degrees of malformation of the Wolffian duct, for example, *Gata3* null mutant mice fail to complete migration to the cloaca ([Grote et al., 2006](#)). In addition to transcription factors, the surface ectoderm close to the mesonephros also plays a role during the formation of the mesonephric duct ([Obara-Ishihara et al., 1999](#)).

Induction of Mesonephric Tubules

As the mesenchymal cells migrate toward the cloaca, they induce the adjacent mesenchyme to form S- or J-shaped epithelial tubules, the mesonephric tubules. However, many regress and the remaining few, those that lie more cranially and are opposite the testis

eventually form the efferent ducts. However, studies by [Sainio et al. \(1997\)](#) suggest that the efferent ducts maybe derived, in part, by the mesonephric duct. The formation of the distinct arrangement of the efferent ducts is unclear but may involve mesonephric tubule branching morphogenesis and/or fusion of individual tubules. During this process it is clear that a specific number of efferent ducts and their patterning are established for each species, and via mechanisms that are not known, the cells of the mesonephric duct migrate toward a single point on the testis and fuse/join/contribute to the rete testis. Sonic hedgehog (*Shh*; [Murashima et al., 2014](#)) has been shown to be a major regulator of some these events, and the transcription factors *Wt-1* and *Six1*, which are expressed in the mesenchyme, regulate the mesonephric tubule number in the cauda/distal region of the mesonephric duct. This data provides evidence that two types of mesonephric tubules, cranial-type, and cauda-type, develop and are differentially regulated ([Sainio et al., 1997](#)).

The number and patterning of the human efferent ducts differs considerably from other species. In addition, in the human, the classical “caput” region comprises mostly efferent ducts, and has very limited epididymal duct contribution, whereas in other species, the caput, including the initial segment, region is only epididymal duct. Therefore, it is important to realize that it is very difficult to compare functions of the human caput with that of other species.

Epididymal disjunction in humans is a condition in which the efferent ducts fail to fuse with the testis. More severe testicular-epididymal fusion anomalies such as complete separation of the testis and epididymis with epididymal atrophy can also occur. Epididymal disjunction is seen in approximately 2%–4% of males but increases significantly to approximately 25% in males that were cryptorchid at birth. Very often these anomalies were only discovered when the adult male underwent surgical procedures for exploration of the tunica vaginalis, congenital hernia repair, and emergencies involving testicular torsion ([Caterino et al., 2014](#)). Therefore, it is important that epididymal abnormalities be detected at orchidopexy or otherwise male infertility, which may be classified as idiopathic, will result.

Elongation and Coiling of the Wolffian Duct

Elongation and coiling are not trivial events in that mouse epididymis elongates from 1 mm to over 1 m, whereas the rat and human epididymis elongates to 3 m and 6 m respectively. It is difficult to examine the development of the human epididymis, and therefore animal models, for example gene knockouts in mice, are used instead. These models have provided clues as to the mechanisms of elongation and coiling, which are probably similar to the mechanisms that occur in the human. At embryonic day 14.5 (E14.5) in the mouse and E17.5 in the rat, the Wolffian duct is straight, and then 2 days later coiling is observed in the most proximal region (putative initial segment region). Coiling gradually progresses along the duct with time, and at E18.5 in the mouse, three-dimensional coiling is initiated (see reviews by [Joseph et al., 2009](#); [Hinton et al., 2011](#)). Elongation occurs via two major events, epithelial cell proliferation and epithelial cell rearrangements, for example, medio-lateral intercalation (convergent-extension; [Xu et al., 2016](#)). Coiling and elongation continue during the postnatal period but now a series of septa divide the duct into a number of segments (10 for the mouse and 19 for the rat). Interestingly, the number and position of septa in the human epididymis is variable. Although there are several mediators of elongation and coiling (see below), it is not clear as to the mechanisms that dictate length and shape. The epididymis must be of the correct length or male infertility will result ([Fig. 1](#)).

Congenital unilateral/bilateral absence of the vas deferens (CUAVD, CBAVD): CBAVD is found in approximately 1%–2% of infertile men and is often associated with mutations of the cystic fibrosis transmembrane conductance regulator (CFTR) gene, whereas CUAVD is less common and is not associated with CFTR gene mutations ([Ong et al., 2017](#)). However, it should be noted that not all patients that carry mutations in the CFTR gene have an absence of the vas deferens. Commonly, in patients carrying CFTR mutations, it is only the caput region, presumably the efferent ducts, that remains, whereas the more distal regions of the epididymis and the vas deferens are absent. This would suggest that the mesonephric duct had either failed to migrate to the cloaca and/or it did migrate but underwent atrophy soon after fusion to the cloaca. The latter suggestion seems plausible because the efferent ducts/mesonephric tubules were present, and were presumably induced to form by the migrating mesonephric duct. The importance of the CFTR gene toward Wolffian duct development is unclear, although since fluid is present in the lumen during development, any changes in fluid secretion resulting in an increase in viscosity would cause luminal blockage and epithelial atrophy.

Regulators of Stabilization, Elongation, and Coiling

The stabilization and differentiation of the Wolffian duct are dependent on several factors, which include sex hormones and growth factors. In the female fetus, the lack of androgens in the hormonal milieu prevents the stabilization of the Wolffian duct, resulting in its regression. In the male fetus, androgens are necessary for Wolffian duct stabilization and later for the highly coordinated morphogenic program that will transform this duct into its adult derivatives ([Welsh et al., 2008](#)).

Androgen Regulation

Androgens are steroid hormones that exert their effects through activation of its cognate androgen receptor (AR), a member of the superfamily of ligand-activated steroid hormone receptor. The AR binds both testosterone and its 5- α -reduced metabolite

Fig. 1 Schematic diagram of mouse Wolffian/epididymal duct development. (A–C) The origin of the epididymis is the intermediate mesoderm. Spatiotemporally distinct intermediate mesoderm at E8.5 gives rise to the Wolffian duct (WD) and metanephric mesenchyme. The anterior intermediate mesoderm gives rise to the pronephros and the whole WD, whereas the posterior intermediate mesoderm gives rise to the metanephric mesenchyme. The WD begins to form from the anterior intermediate mesoderm at E8.5 and grows posteriorly reaching the urogenital sinus at E9.5. Concomitantly, the pronephros regresses through apoptosis. The WD induces the formation of mesonephric tubules from the mesenchyme (nephric cord) adjacent to the WD in a cranio-caudal manner. At the caudal end of the WD, the metanephros is initiated by ureteric bud formation through the interaction between WD epithelia and the metanephric mesenchyme at E10.5. (D) After gonadal sexual differentiation begins, the WD in the female embryo regresses from cranial to caudal and the WD in the male embryo is stabilized. The cranial set of mesonephric tubules connected to the WD is stabilized while the caudal set of mesonephric tubules regresses via apoptosis. (E) In the male embryo, the stabilized WD begins to coil from the cranial portion at E15.5. The duct continues to elongate and coil throughout development. (F) Ductal elongation and coiling continue after birth. The single-layered ductal epithelia undergo differentiation between P15 and P44. During this time, the regions of the epididymis, initial segment, caput, corpus and cauda, and the septa become morphologically distinct. Sperm transport through the duct begins at approximately P35. IM, intermediate mesoderm; UGS, urogenital sinus; IS, initial segment. Modified from Murashima, A., Xu, B. and Hinton, B.T. (2015b). Understanding normal and abnormal development of the Wolffian/epididymal duct by using transgenic mice. *Asian Journal of Andrology* **17**, 749–755; and reproduced by kind permission from the Asian Journal of Andrology.

dihydrotestosterone (DHT), a more potent androgen. AR activity is essential for Wolffian duct development because severe mutations that completely disrupt the AR activity in XY males are associated with the absence of epididymis/vas deferens, whereas patients with milder mutations that allow residual AR activation display normal Wolffian duct development (see review by Shaw and Renfree, 2014). Consistent with this clinical observation, Wolffian duct derivatives are absent in AR knockout (ARKO) mice (Welsh et al., 2009). Testosterone itself, but not DHT, has been shown to orchestrate a dominant role in the AR-dependent Wolffian duct development. In fact, DHT is not present in the Wolffian duct until epididymal differentiation is complete, and 5- α -reductase-deficient patients (which prevents conversion of testosterone to DHT) show normal Wolffian duct differentiation. Since AR acts as a ligand-dependent transcription factor, it is likely that regulation of expression of specific target genes (classical genomic androgen signaling) plays an important role in AR-dependent Wolffian duct development. Role of several androgen-targets in cell proliferation/elongation and coiling during the embryonic period include factors such as *inhibin beta A* (*Inhba*), *Wnt5a*, *Fgf8*, *Dusp6*, *Hoxa10*, various growth factors, among others (see review by Murashima et al., 2015a,b). However, the responsible downstream events and molecular and cellular determinants of androgen action are still unclear.

A schematic representation of the timeline key events for androgen action in Wolffian duct development in male Wistar rat fetuses is shown in Fig. 2. Wolffian duct development induced by androgens has been proposed as a biphasic

Fig. 2 Schematic diagram representing key events of androgen action during Wolffian duct development in male Wistar rat fetuses. Each embryonic age (E0.5–E21.5 days) is indicated in the timeline. The presence of spermatozoa in vaginal smears the following morning was considered evidence of mating and the time was defined as E0.5. The male programming window, as well as the periods during which the Wolffian duct is undergoing stabilization and morphological differentiation to originate a fully functional adult epididymis, vas deferens, and seminal vesicle is indicated. As a reference, the isolated Wolffian duct at both ages E17.5 (straight duct) and E21.5 (differentiated/developed duct) is shown. In the rat, testis differentiates at E13.5 and begins to secrete testosterone at E15.5, 1 day after the initial detection of AR protein in the mesenchymal cells of the Wolffian duct. Then, at E18.5 a peak in the testosterone plasma concentration is observed and AR is localized in both mesenchymal and epithelial cells. Wolffian duct development induced by androgens has been proposed as a biphasic process: testosterone first stabilizes the duct in males and then the duct undergoes morphological differentiation into the epididymis, vas deferens and seminal vesicle (not shown). The morphological differentiation of the Wolffian duct, which starts at E19.5, is programmed between E15.5 and E17.5 in the rat. The parallel in human timeline of the rat masculinization programming window is likely 8–14 weeks of gestation.

process: testosterone first stabilizes the duct in males and then morphologically differentiates it into the epididymis, vas deferens, and seminal vesicle. The morphological differentiation of Wolffian duct, which starts at E19.5, is programmed between E15.5 and E17.5 in the rat (Fig. 2). In humans, this rat masculinization programming window is likely to occur between 8 and 14 weeks of gestation (Welsh et al., 2008). Interestingly the spatio-temporal patterns of Wolffian duct morphogenesis in rat and mouse are heterochronic and the initial coiling of the future epididymis observed in the rat at E19.5 is seen earlier at E16.5 in the mouse (see review by Hinton et al., 2011).

Different experimental approaches, including the use of AR pharmacological tools and genetic mutant models, have demonstrated that dynamic mesenchymal–epithelial interactions under control of AR/testosterone signaling drives androgen-dependent mesenchyme-derived molecules that act as Wolffian duct epithelial paracrine regulators during the Wolffian duct morphogenesis. Androgens exert their effects on the Wolffian duct epithelium indirectly by androgen-dependent mesenchymal-derived factors and just after E18.5, as well through AR that is now also found in the WD epithelium. Mesenchymal ARs are needed for Wolffian duct stabilization, growth and coiling, while epithelial ARs are needed for later development and adult function (see reviews by Shaw and Renfree, 2014; Murashima et al., 2015a). Thus, Wolffian duct morphogenesis requires direct androgen action on the mesenchyme to maintain its survival and it is mesenchyme–epithelium crosstalk that determines the regional specialization of the epithelium. The complex signaling network involving molecules of mesenchymal origin which instruct epithelial growth under control of androgen action, however, is still poorly understood.

Androgen action during the masculinization programming window, which occurs several days prior any sign of Wolffian duct morphological differentiation (Fig. 2), has been proposed as sufficient to fully promote Wolffian duct development. Genetic mutations in AR or treatment with AR antagonists to block androgen signals during the male programming window result in regression of the Wolffian duct and an absence of the epididymis in adult males. Thus, disturbances during this period have the potential to lead to clinical pathologies with long-lasting consequences throughout life (see review by Skakkebaek et al., 2016). Disorders in androgen synthesis and/or action have been linked to atypical development of the male reproductive tract. At least 50 different congenital abnormalities of urogenital formation are recognized by the medical term of disorders of sex development (DSDs). Recently, it has been proposed that reproductive problems such as cryptorchidism, hypospadias, testicular germ cell cancer, low

sperm count, and primary hypogonadism have a common origin in fetal life as a result of impaired testosterone synthesis or action during the masculinization programming (more recently been hypothesized to be testicular dysgenesis syndrome, TDS) (Welsh et al., 2008; van den Driesche et al., 2017). In addition to genetic causes, environmental exposure of fetal testes to androgens or antiandrogen endocrine disrupting chemicals is recognized as important factor to TDS susceptibility.

Hox Genes

Hox genes are members of the homeotic transcription factor family that play a key role in controlling the body plan along the cranio-caudal axis (also referred to as anterior–posterior), and specify segment identity of tissues within the embryo. Mutations in *Hox* genes result in homeotic transformation of that tissue, that is, one part of that tissue develops into another part of the tissue. *Hox* genes are highly expressed within the developing Wolffian duct, particularly *Hoxa9*, *Hoxd9*, *Hoxa10*, *Hoxd10*, *Hoxa11*, *Hoxa13*, and *Hoxd13* (Snyder et al., 2010). Mice expressing null mutations of *Hoxa10* and *Hoxa11* resulted in the homeotic transformation of the vas deferens in which where the straight proximal region was transformed into a highly coiled segment, typical of the cauda region (Branford et al., 2000). However, the mechanisms by which *Hox* genes regulate Wolffian duct morphogenesis and segmentation are not known.

Inhibin Beta A

This gene is present in proximal Wolffian duct mesenchyme and mesonephros from both male and females before E12.5 in rat, but later its expression becomes androgen dependent. *Inhibin beta A* knockout mice (Tomaszewski et al., 2007) show pronounced Wolffian duct coiling defects. Cell division was lower in the knockout compared to wild-type but not zero, thereby suggesting that coiling and elongation via cell proliferation are separate events. Apoptosis was not observed in either the wild-type or knockout Wolffian ducts. In situ hybridization experiments showed the presence of *Inhibin beta A* in the mesenchyme whereas its downstream signaling components, SMAD2/3, were localized within the epithelial cells. Therefore, the data would suggest that factors within the mesenchyme, for example, *Inhibin beta A*, regulate the coiling and partially the cell proliferation rate during embryonic development of the Wolffian duct. There is also evidence that the effects of *inhibin beta A* in coiling control can be at least in part mediated by upregulation of AR in the epididymal epithelium.

Growth Factors

Different growth factors participate in the regulation of gene expression, especially through epithelial–mesenchymal, acting as androgen-regulated mediators in the developing Wolffian duct (see review by Murashima et al., 2015a). In addition to FGF8 signaling, FGF ligands can also bind and activate alternatively-spliced forms of four tyrosine kinase FGF receptors (FGFRs 1–4). FGFR1 is expressed in the mesenchyme, while FGFR2 is in the epithelium maintaining the Wolffian duct and mesonephric mesenchyme. FGFR2 in the epithelia is suggested to maintain the caudal part of the WD by regulating cell proliferation. Epidermal growth factor (EGF) and its receptor (EGFR) signaling are also active during the developing Wolffian duct. While it has been suggested that EGF can maintain development of isolated Wolffian ducts in culture in the absence of a testis, antibodies against EGF and EGFR can prevent ductal development in the presence of a testis. The association of EGF and antiandrogens can prevent Wolffian duct stabilization, suggesting that EGF-induced effects in the developing duct are under androgen regulation. AR can either directly regulate expression/activity of growth factors, or indirectly through other androgen-regulated target molecules.

Protein Tyrosine Kinase 7 (Ptk7)

Ptk7 is a component of the noncanonical Wnt/planar cell polarity and the *Wnt* canonical signaling pathway. In a number of tissues the protein functions in cell migration, cell adhesion, cell polarity, cell proliferation, and the organization of the actin cytoskeleton. During the development of the Wolffian duct, evidence suggests that Ptk7 regulates epithelial planar cell polarity and epithelial cell rearrangements such as medio-lateral intercalation (convergent extension) and radial intercalation of the mesenchymal cells closely surrounding the duct (Xu et al., 2016). Further studies revealed that planar polarized cells also expressed polarized distribution of active myosin II, which is necessary for cell to migrate and intercalate correctly. Loss of Ptk7 resulted in a shortened epididymis, which in turn resulted in loss of sperm motility. Therefore, an epididymis that is not of the correct length will result in male infertility.

Epithelial Canonical Wnt/ β catenin

Studies have provided evidence that the canonical Wnt/ β catenin signaling pathway plays a crucial role during Wolffian duct morphogenesis (Kumar et al., 2016). Wnt/ β catenin signaling, as shown by using Wnt reporter mice, is active in the duct during the embryonic period and later in the adult, to a limited region in the caput (segments 2–4). Loss of signaling of this pathway, whether by using pharmacological reagents and mouse null mutations, results in a duct that fails to undergo elongation through a reduction in cell proliferation and increase in cell apoptosis, and coiling.

β -Defensin SPAG11C (Sperm-Associated Antigen 11C)

SPAG11 is a member of the β -defensin multigenic family of epithelial-secreted peptides that present both antimicrobial and immunomodulatory properties, as well as ability to regulate sperm function. Its expression drastically changes during Wolffian duct/epididymal development, since it is observed mainly in mesenchymal cells in the developing rat Wolffian duct, in contrast to its predominant localization in epithelial cells of the postnatal and adult epididymis. Manipulation of the androgen status in rat Wolffian duct organotypic cultures showed SPAG11C as a downstream target of AR signaling. In addition, incubation of isolated Wolffian ducts with recombinant SPAG11C protein impaired duct morphological differentiation as a result of reduced epithelial cell proliferation (Ribeiro et al., 2017). These observations implied a putative role for SPAG11C in epididymal morphogenesis. The contribution of other β -defensins in shaping Wolffian duct morphogenesis in response to different developmental cues is still under investigation (Ribeiro et al., 2016).

Lumicrine Fluid Factors

Although testicular luminal fluid factors, or lumicrine factors, play a role in the regulation of adult initial segment in the epididymis, lumicrine factors do not appear to play a role in Wolffian duct elongation and coiling. When E14.5 mouse Wolffian ducts are cultured *in vitro*, they elongate and coil without the testis, but androgens are necessary (Hinton et al., 2011). However, in the postnatal Wolffian duct/epididymis, lumicrine factors are crucial for maintenance of cell proliferation.

Glossary

Blood–testis barrier The barrier formed between Sertoli cells, which divides the seminiferous epithelium into basal and adluminal compartments and consists of a morphological tight junctional component that regulates the entry and exit of molecules and passage of early spermatocytes through the barrier and an immunological competence that results in an immune-privileged site for the protection of differentiating germ cells.

Efferent ductules Small tubules that connect the external rete testis and epididymis and support an epithelium consisting of ciliated and absorptive non-ciliated cells.

Extratesticular rete testis A type that consists of flattened irregular-shaped anastomosing sacs and channels lined by a cuboidal to squamous epithelium and located adjacent to the tunica albuginea, which is found in rodents.

Mediastinal rete testis A type that has irregular-shaped anastomosing channels lined by a cuboidal to squamous epithelium and extending from the tunica albuginea into the testicular core, which is found in primates, including man and all large mammals.

Primary cilium A single non-motile cilium, with a 9 + 0 axonemal complex, found on nearly every cell at one point in development, which serves unique functions such as chemical sensation, signal transduction, cell cycle, and cellular growth.

Seminiferous tubule The testicular structure lined by an epithelium consisting of non-dividing Sertoli cells and germ cells, which undergo the process of spermatogenesis to produce sperm that are released into the lumen and transported into the rete testis.

Transitional region The short, narrow segment where seminiferous tubules open into the rete testis, and which are lined by tall, modified Sertoli cells, called transitional cells that protrude into the lumen in such a manner as to form a plug or valve like structure angled towards the rete testis and a subset of cells may serve as stem cells capable of proliferation.

Tubulus rectus Only present in some species, this is the straight tubule that connects the transitional region to the rete testis anastomosing spaces, often considered the proximal part of the rete, and in some species the epithelial cells may differ from those in the rete proper by containing an abundance of glycogen.

Organization of the Rete Testis

The rete testis is a continuous chamber of flattened or irregular-shaped anastomosing channels into which seminiferous tubules empty their luminal contents of spermatozoa, proteins, water, and other substances (Leeson, 1962; Dym, 1976; Roosen-Runge and Holstein, 1978; Setchell, 1978). Newly released spermatozoa and fluids are transported rapidly from this flattened cavernous space through the tunica albuginea into the numerous efferent ductules that connect to the head of the epididymis. There are two basic designs observed for rete testis organization (Fig. 1): (a) mediastinal and (b) extratesticular.

Mediastinal Rete Testis

Mediastinal rete testis is robust and surrounded with considerable amounts of dense connective tissue (Figs. 1 and 2). It is found in primates, including man and all large mammals, such as dogs and bulls (Wrobel, 2000). These irregular-shaped anastomosing channels extend from the tunica albuginea at the hilus through connective tissue septa in a fan-like manner into the testicular core, approximately 1/3 of the testis in man, providing a secure attachment. The rete epithelium of larger mammals is surrounded

Fig. 1 (A) Illustrations showing the mediastinal and extratesticular rete testes (green). Mediastinal rete is found in primates, including man and all large mammals. Extratesticular rete is found in rodent species, such as mice and rats. Seminiferous tubules open into the rete testis, which collects the sperm and tubular fluid and channel them through the tunica albuginea into the efferent ducts that merge into the caput epididymis. (B) LM of the mediastinal rete testis outlined in red, which extends into the center of the dog testis. Seminiferous tubules extend as lobules from the rete testis to the tunica albuginea connective tissue capsule that surrounds the outside of the testis. Bar = 700 μ m. (C) LM of the extratesticular rete testis of the mouse outlined in red. It is located at the edge of the testis, with seminiferous tubules underneath and tunica albuginea on the outside. Rete testis exits at the testicular hilus, where blood vessels also penetrate the capsule. Bar = 250 μ m.

mostly by thick bundles of collagen and interspersed with the blood vasculature, lymphatic vessels and contractile myoid cells or bundles of smooth muscle.

Extratesticular Rete Testis

The entire extratesticular rete testis is located adjacent to the tunica albuginea and is found in rodents (Figs. 1 and 2). This type of rete extends only a short distance into the testis, but penetrates the tunica albuginea and extends briefly outside the testicular capsule (Hess, 2014). Smooth muscle or myoid cells do not line the base of this epithelium, in contrast to the efferent ductules and

Fig. 2 (A) LM of the rete testis of the dog consists of flattened chambers surrounded by collagen connective tissue bundles (CT) and adjacent seminiferous tubules (ST). Leydig cells (LC) are found between the seminiferous tubules and the rete testis. The rete epithelium is low cuboidal to squamous. Bar = 100 μ m. (B) LM of the rete testis (RT) of the mouse consists of anastomosing chambers located adjacent to the tunica albuginea capsule (TA) of the testis. There is very little connective tissue surrounding the chambers that are bulging against the seminiferous tubules (ST), with Leydig cells (LC) in between. Bar = 100 μ m. (C) Schematic representation of the rat rete testis (green) is shown in an illustration modified from a drawing taken from the archives of Dr. Yves Clermont, McGill University. The two ends of a seminiferous tubule open into the rete cavernous spaces that are located at the hilus region, which extends into the testis and exits through the tunica albuginea and empties into the small ductuli efferentes tubules that continue to the epididymis. The rete testis epithelium is short cuboidal to squamous, compared to the taller stellate shaped Sertoli cells of the seminiferous epithelium and columnar epithelium of the ductuli efferentes.

epididymis. As in the case of the mediastinal rete, the extratesticular rete opens into a varying number of tubes of small diameter, the efferent ductules, depending on the species.

Transitional Region

Seminiferous tubules of the testis are long narrow and convoluted tubules ($\sim 250 \mu$ m in diameter) that terminate with a hairpin-like turn that opens at each end into the rete testis through short, narrow segments called the transitional region or zone (Dym, 1974; Hermo and Dworkin, 1988; Nakata et al., 2015). These segments (Fig. 3), unlike the seminiferous tubule proper, are lined by tall, modified Sertoli cells (also called transitional cells). The latter show tight junctions apically, and their free apical processes often protrude into the lumen in such a manner as to form a plug or valve like structure angled towards the rete testis (Hermo and Dworkin, 1988). Spermatozoa are not produced in this region, which shows rare germ cells, although in hamsters

Fig. 3 (A) Low power LM photo of the rat rete testis junction with the seminiferous tubule (ST). The boxed area of the transitional region is magnified in (B). The rete testis is located adjacent to the tunica albuginea (TA) capsule. A short, straight tubule, or *tubulus rectus*, can be seen between the transitional region (in the *black box*) and the rete testis sacs. Bar = 100 μ m. (B) Higher magnification of the transitional region (outlined by *arrows*) between the seminiferous tubule (ST) and rete testis. Germ cells including pachytene spermatocytes (Ps) are present in the seminiferous tubule epithelium, but are missing in the transitional region, where only Sertoli cells (SC) are present and whose apical processes protrude into the lumen in the direction of the rete. Bar = 25 μ m. (C) A lower LM photo of the mouse rete testis/efferent ductule junction, which is located outside of the tunica albuginea. The rete testis epithelium (RT) is squamous, while the efferent ductule epithelium is short columnar in height and contains nonciliated (Nc) and ciliated (Ci) cells. At the junction, the epithelium changes abruptly from squamous to columnar, but there are pockets of ductuli efferentes epithelium interspersed between the rete epithelium. Occasional ciliated cells (*) are seen within the rete epithelium, but only in this junctional region. Bar = 50 μ m. (D) LM higher magnification of the mouse rete testis (RT)/efferent ductule junction showing the squamous epithelium, with one ciliated cell (*) in the rete testis section between the pockets of efferent ductule epithelium (ED). The efferent ductule has ciliated cells with motile cilia (Ci) and nonciliated cells (Nc) showing endocytic vesicles. Bar = 30 μ m.

spermatogonial stem cells are present in higher concentration (Aiyama et al., 2015). Transitional epithelial cells have adult Sertoli cell-like features such as microtubules in the apical cytoplasm and an elaborate network of endoplasmic reticulum, as well as phagocytotic activity and active endocytosis. However, other features suggest these cells are different, such as interdigitations of their lateral plasma membranes, apically located tight junctions and a unique thick and convoluted basement membrane structure. Immunostaining with SOX-9, WT1 and proliferation markers reveals that these cells are undifferentiated Sertoli cells capable of proliferation in the adult testis (Aiyama et al., 2015; Figueiredo et al., 2016; Kulibin and Malolina, 2016).

Rete Testis Epithelium

The seminiferous tubule transitional region changes abruptly from a tall columnar epithelium into a low cuboidal epithelium to form the characteristic structural appearance of the rete testis (Figs. 2 and 3). In some species, the initial connection with the rete is

a narrow, straight tubule that has been called *tubulus rectus* (Osman and Plöen, 1979) and is considered to be an initial region of the rete, but sometimes having modified epithelial cells. Rete testis epithelial cells show some species variation, with some cells being more squamous and others short columnar. In all species, the nuclei, with deep infoldings of the nuclear envelope, lie elongated and parallel to the basement membrane. The epithelial cells show numerous lateral plasma membrane folds and interdigitations, but the apical membrane is fairly smooth revealing only a few short microvilli and occasional small invaginations or pits of the clathrin-coated and uncoated variety. A long, single primary cilium is at times observed extending from the epithelial cells into the lumen (Dym, 1976). The cytoplasm shows components of an active endocytic apparatus (Morales and Hermo, 1983; Hermo and Dworkin, 1988), including endosomes, multivesicular bodies (MVBs) and few lysosomes. Fluid-phase and adsorptive endocytosis have been demonstrated along with receptor-mediated endocytosis. The cytoplasm also contains cytoskeletal elements, scattered mitochondria, with some aggregating in the basal region, Golgi apparatus, and endoplasmic reticulum. Lipid inclusions are also observed, and in some species the rete epithelium can be loaded with glycogen inclusions (Fawcett and Dym, 1974).

Efferent Duct Connection

Rete testis penetrates the thick tunica albuginea proximally as flattened channels but opens distally into expanded spaces (Hess, 2014), where the squamous epithelium meets the openings of a varying number of efferent ductules (Figs. 2 and 3). At this merging point there is a sudden change from the cuboidal to squamous rete testis epithelium to the columnar epithelium of the efferent ducts, which is identified by the projection of long cilia into the lumen, characteristic of ciliated cells. The junctional area often consists of efferent duct epithelium interspersed between rete testis squamous epithelia (Fig. 3).

Rete Testis Function

Rete testes have an appearance consistent with a space that is used for the collection of seminiferous tubular fluids and spermatozoa that are to be distributed into the numerous separate openings of the emerging efferent ductules. In rats, transport through the long efferent ductules is rapid (45 min) (Dym, 1976). It is also assumed that sperm are transported through the rete in a rapid manner. There is limited evidence that rete testis is active in secretion of proteins into the lumen, but rather its epithelium participates in fluid-phase, adsorptive and receptor mediated endocytosis (Hinton and Keefer, 1983; Morales and Hermo, 1983). The lack of water protein channels, aquaporins 1 and 2 in the rat, supports the conclusion that the rete testis does little to increase the concentration of sperm in the lumen. In fact, this is a major function of the efferent ductules amply decorated with numerous aquaporins, which remove about 90% of the luminal fluids (water) coming from the testis and derived from Sertoli cells (Hermo and Smith, 2011). The flow of fluid through the rete testis is unaffected by LH, FSH, prolactin, and the prostaglandins (Hinton and Setchell, 1993). Rete testis fluid, except for some modifications, is similar to seminiferous tubular fluid, and both fluids differ significantly from blood plasma. Rete testis differs from seminiferous tubule fluid by being isotonic with blood plasma, possibly due to the ability to move some ions such as sodium and chloride from the surrounding vasculature (Setchell, 1978).

Considerable evidence suggests that a major function of the rete epithelium is the endocytosis of proteins, as suggested by the higher concentration of total protein in the seminiferous tubule fluid as compared to that of the rete fluid (Setchell, 1978). Such proteins are internalized by coated pits and end up in lysosomes where they are degraded. The secreted proteins of Sertoli cells, namely androgen binding protein, sulfated glycoprotein-2/clusterin and sulfated glycoprotein-1, have all been demonstrated to be endocytosed by the rete epithelial cells (Morales and Hermo, 1983; Hermo et al., 1991, 1992, 1998). These proteins appear to be directly or indirectly related to late spermatids forming in the testis, where they may have a functional role. However, as future sperm leaving the seminiferous tubules, all three of these proteins dissociate from sperm and appear free in the rete lumen to be endocytosed and degraded. However, the rete epithelium is also involved in transcytosis, an event that allows selective proteins to be taken up by small uncoated pits and vesicles of the apical cell surface which are then delivered to the lateral plasma membrane. After fusion with this membrane the contents of these vesicles are released into the intervening lateral intercellular spaces allowing them to be free to access the blood vessels of the underlying connective tissue areas (Morales and Hermo, 1983). The nature and functions of these proteins has yet to be documented, but this is an event also noted for the epithelial cells of the vas deferens (Hermo and de Melo, 1987).

Of particular note, the long primary cilium found extending from rete epithelial cells (Dym, 1976) into the lumen may serve as chemical sensory detectors, but their signaling pathways have not been uncovered. Although the blood–testis barrier, at the basally located Sertoli–Sertoli cell junctional complexes of seminiferous tubules (Dym and Fawcett, 1970; Hinton and Keefer, 1983), provides innate resistance to autoimmune reactions, the apical Sertoli–Sertoli complexes of the transitional zone is susceptible. This segment contains resident intraepithelial lymphocytes and macrophages, which make up approximately 20% of the interstitial cells providing a region capable of rapid autoimmune responses (Takahashi et al., 2007).

Interestingly in rodents and mammals, seminiferous tubules, efferent ductules and the epididymis are enveloped beneath the basement membrane by smooth muscle cells referred to as myoid cells (Oliveira et al., 2016). The latter form distinct layer(s) enveloping these tubules. As sperm emanating from the seminiferous tubules are immotile, myoid cells contract and move sperm into the lumen of rete testis. However, in rodents the rete testis lacks myoid cells. Hence it is proposed that the role of the efferent ductules is to propel sperm out of the rete lumen. A major function of the epithelial cells of the efferent ductules is to absorb water (90%), via a number of aquaporin protein channels located at the apical pole of their epithelial cells, from the lumen into the underlying connective tissue spaces (Hermo and Smith, 2011). The volume and rapid uptake of water through this epithelium

must generate a suction-like pressure in the rete whereby the sperm located there would be propelled out of the rete lumen into the efferent ductules.

Another caveat to this story is the relevance of the plug (valve) in the transition zone. As sperm are moved out of the seminiferous tubules by myoid cells, they enter the transition zone. Here myoid cells move sperm to the rete testis, and as sperm leave the transition zone they would push aside the plug oriented towards the rete lumen. This plug or valve-like structure would however prevent regurgitation of sperm and substances from the rete lumen back into the lumen of seminiferous tubules (Hermo and Dworkin, 1988). Its presence is of relevance in today's stem cell transplantation studies as will be explained in the next section.

Rete Testis Site for Stem Cell Transplantation

In the mid-1970s, Martin Dym identified a specific area where the rete testis was positioned in the gross structure of the adult rat testis (Dym, 1976). It was seen as a small opaque spot or window at the upper pole of the testis, and at the point where the efferent ductules emerged. It was also adjacent to where the vascular channels penetrated the testis, that is, the hilus of the testis. Interestingly in rodents, the efferent ductules and vascular channels are surrounded by a large fat pad and care has to be taken in separating one from the other. This is particularly relevant in studies related to efferent duct ligation. Once this is done, the oval window can also be found and origin of the efferent ductules located. This window has become functionally important over the years, as it is the site where various substances (electron dense tracers), for example, ferritin and thorotrast, could be injected into the lumen of the rete testis, which is accomplished by introducing these tracers with a 30-gauge needle attached to a syringe and the use of a dye to visualize their entry into the rete lumen (Dym, 1976; Morales and Hermo, 1983).

From personal observations (Hermo and Morales, unpublished) the needle is administered into the rete lumen at the window, and with gentle pressure, the tracers and dye in a fluid medium are injected into the rete. It should be noted that just the tip of the needle has to puncture the rete and that a deep entry is fatal; in this case the tracers enter the interstitial space of the testis. However, when introduced into the rete lumen these tracers also enter the lumen of the efferent ductules. This is in fact the normal route and flow of substances, that is, from seminiferous tubules into the rete lumen and hence into the efferent ductules. Administration of electron dense tracers into the rete lumen has been profitable for definition of the endocytic organelles of both the rete testis epithelium and that of the efferent ductules, and is visualized by electron microscopy (Hermo and Morales, 1984; Morales et al., 1984; Hermo et al., 1991). In various time course studies, the internalization of these tracers by the rete and efferent ductule epithelial cells was evaluated. At early time points, tracers appear in coated and uncoated pits of the cell surface, small subsurface vesicles and endosomes (1–5 min), followed by MVBs (15–30 min) and lysosomes (1 h). Thus a fortuitous site for injection of various substances resides in the rete testis and this can be visualized with the naked eye.

This approach also has permitted the analysis of endocytic activity by Sertoli cells (Morales et al., 1985). However, for tracers injected into the rete lumen to be able to enter the seminiferous tubule lumens, one has to apply an ample amount of pressure to penetrate the plug formed by the Sertoli cells of the transitional zone. After repeated trials and errors, and the proper positioning of the needle into the rete lumen, which is purely a chance thing, one can be successful and enter the rete allowing the entry of tracers directly into the seminiferous tubule lumen. This takes a steady hand and a lot of practice. However, once the plug is penetrated and the tracers and dye are administered properly, they can be seen to flow in a retrograde manner filling the lumen of the seminiferous tubules. The flow occurs on its own without any added force on the needle, and with time each tubule in the testis becomes progressively filled with tracer and dye. It should be pointed out that in many cases (50% of the time), the tracers do not enter the seminiferous tubule lumen but enter the interstitial space of the testis. In such cases there is no flow of fluids and thus one has to re-try to position the needle into the rete lumen. In fact, the rete lumen is a flattened space and attempting to get the needle into this invisible space is highly problematic. Thus practice makes perfect but once perfected, the method can provide solid results.

The rete testis injection site became clinically relevant over the past decades, as Ralph Brinster and colleagues began to harvest germline stem cells from normal animals and introduce them into infertile and germ cell-depleted male, lacking the capability to produce sperm (Brinster, 2002). Using a reporter (LacZ) transgene in the donor animal it was possible to show that true stem cells were transplanted, as only spermatogonial stem cells would be capable of sustained spermatogenesis in the recipient testis. The donor stem cells were injected into the seminiferous tubule via the rete testis of recipient males and the stem cells appeared to migrate through the seminiferous epithelium to reside on the basement membrane of the tubules, where they subsequently underwent the process of spermatogenesis.

Another possible function of the rete could be to prevent damage to the blood–testis barrier after efferent ductule blockage. It has been observed that in male transgenic (Tg) mice constitutively expressing Notch1, the epithelial cells of the Tg tubuli recti and rete testis were not abnormal, but the rete testis lumen was highly dilated and contained numerous spermatozoa, suggesting a blockage downstream (Lupien et al., 2006). Data revealed a blockage of the efferent ducts at their interface with the rete, as also noted by absence of spermatozoa in the epididymis of all adult Tg mice, without seriously affecting spermatogenesis. Hence in abnormal situations of efferent duct blockage, the rete testis is capable of temporary dilation to accommodate the adverse situation and thus prevent the possible disruption of blood–testis barrier function (Nykänen and Korman, 1978; Hess, 2014).

Conclusion

The rete testis is a continuous chamber of flattened and irregular-shaped anastomosing channels lined by squamous to cuboidal epithelial cells adjacent to the tunica albuginea (rodents) and extending centrally into the testis of larger mammals including

man. The rete testis serves as a conduit and point of exit for newly released spermatozoa and fluids emanating from seminiferous tubules. The epithelial cells are highly active in endocytosis, with several proteins derived from Sertoli cells and sperm emanating from seminiferous tubules. Thus while a seemingly passive chamber, the rete has important roles in fine-tuning the lumen for sperm as they enter the efferent ducts. Of clinical significance, the rete testis has over many decades been used as an appropriate site to inject stem cells into the lumen of seminiferous tubules to restore a deficient or reduced spermatogenesis. It may also serve in obstructions of the efferent ducts to expand and prevent disruption of the blood–testis barrier.

Glossary

Blind-ending tubules Small-diameter tubules arising from developmental anomalies that grow out from rete testis, efferent ducts or the epididymis on one end but do not connect on the other end and appear to have undeveloped epithelia.

Common efferent ducts The terminal region where the tubule joins the epididymis, as a single tubule in rodents but as individual tubules in larger mammals, with both types having a narrow lumen.

Conus efferent ducts The central region between rete testis and epididymis, where the highly coiled tubules begin to merge and the lumen becomes more narrow.

Fluid reabsorption Rapid transport of fluids, including ions, water, selected proteins and other molecules, by the ductal epithelium in an isosmotic equilibrium from the lumen into the interstitial space containing the vascular system.

Motile cilia Finger-like projections on the apical surface of specific epithelial cells, with a 9 + 2 axonemal complex, capable of coordinated movement that helps to stir the luminal fluids.

Primary cilium A single non-motile cilium, with a 9 + 0 axonemal complex, found on nearly every cell at one point in development, which is involved in unique functions such as chemical sensation, signal transduction, cell cycle and cellular growth.

Proximal efferent ducts The region originating at the rete testis as individual, straight tubules with a wider lumen and more dilute concentrations of sperm.

Rete testis An irregularly-shaped chamber of anastomosing channels, lined by a cuboidal to squamous epithelium, extending from the tunica albuginea and connecting to the separate efferent ductules.

Nomenclature

AR Androgen receptor

ESR1 Estrogen receptor 1

ESR2 Estrogen receptor 2

AQP1 and 9 Aquaporin 1 and 9

SLC9A3 Na⁺/H⁺ exchanger-3

CAR2 Carbonic anhydrase 2

CFTR Cystic fibrosis transmembrane conductance regulator

SGP-1 and 2 Sulfated glycoproteins 1 and 2

E2 17β-Estradiol

*Esr1*KO Estrogen receptor 1 knockout

*Ar*KO Aromatase knockout

T Testosterone

DHT Dihydrotestosterone

DES Diethylstilbestrol

Organization of the Efferent Ductules

Efferent ductules, previously called vasa efferentia, are small, delicate and parallel tubules that connect the rete testis with the epididymal duct (Illo and Hess, 1992; Hess, 2002). They begin as a series of individual straight ducts originating from the rete testis in all mammalian species, but as enlarged chambers with folded mucosa in avian species. As the ductules extend toward the epididymis they become highly convoluted and progressively smaller in diameter. Efferent ducts are organized into two basic designs, depending on the species (Fig. 1): (1) a funnel and (2) parallel coils. The funnel type of ductule is formed by merging of the proximal ducts, arising separately from the rete testis, until they form a single, very small common duct that enters the head or initial segment of the epididymis. This formation is typically observed in smaller mammalian species, such as rodents. The parallel coil formation is found in larger mammals and birds (Illo and Hess, 1994; Hess, 2002). This design consists of numerous, adjacent coils of efferent ductules arising from the rete testis, with most of these ducts remaining independent, rather than merging, and thus providing multiple entries into the initial region of the epididymis. In man, the more caudal efferent ducts (referring to their position as

Fig. 1 Two basic types of efferent ductule organization are illustrated. (A) Funnel-like formation that is seen in smaller mammals. Individual proximal or initial region ductules, arising from the rete testis, merge to form a single, common duct that enters the head of the epididymis. Histology of this design shows the proximal ducts having a wider lumen than those in the conus and common duct regions, near the initial segment of the epididymis. A connective tissue capsule is seen on the outer edge but the epididymal fat pad is seen underneath. (B) Formation of parallel coils is found in larger mammals and man. Most of the individual proximal efferent ducts, connected to the rete testis, tend to stay separated, with only a few ducts merging in the cephalic region of the epididymis. Thus, there are numerous separate entries of the coiled efferent ducts into the caput epididymis. Histology of this organization shows the separate ducts surrounded by thick areas of connective tissue. The proximal ducts have a wider lumen than ducts in the distal region, near the initial segment of the epididymis.

they exit the testis) tend to join the epididymis independently, without merging. However, many of the more cranial ducts show some looping and merging to form a very short common duct (Yeung et al., 1991). With both types of organization, there can be numerous proximal efferent ductules arising from the rete testis. However, considerable variation in the number of proximal ductules is found, even within a species. For example, the rat has between 2 and 8 proximal ductules and in man the number ranges from 6 to 15.

The proximal efferent ductules are typically straight and have a wider lumen than those found in the more distal regions, closer to the epididymis. The coiled region of ductules is referred to as the conus vasculosus or "conus". In rodents, the ducts begin to merge in the conus to form a single tubule called the "common duct" that penetrates the connective tissue capsule of the caput epididymis. In man and larger mammals, the coiled ductules form several different types of junctions with the epididymis, as some exhibit end-to-end and others end-to-side junctions (Yeung et al., 1991). In larger mammals and birds, the efferent ducts are embedded entirely in thick bundles of connective tissue that are shared with the head of the epididymis and occupy a major portion of the caput (Yeung et al., 1991). The thick bundles of collagen attach the epididymal head to the hilus of the testis, where blood vasculature enters and the rete testis exits. In rodents, the common duct only shares a very small portion of the caput epididymis, adjacent to the initial segment, and the remainder of the efferent ducts are found in loose connective tissue and an extensive epididymal fat pad that extends between the testis and head of the epididymis, which allows for easy isolation of the individual ducts (La et al., 2012).

Development

Efferent ductules originate from the mesonephros and associated embryonic kidney tubules (Hess, 2002). During development, these ductules are the first site of epithelial androgen receptor (AR) expression in the male reproductive tract (Cooke et al., 1991).

Fig. 2 Blind-ending efferent ducts are recognized by their smaller luminal diameters, a thicker coat of surrounding connective tissue and a more regressed epithelium. These aberrant ductules are typically segregated from the normal ducts. Bar = 40 μ m.

Estrogen receptors are also expressed first in this region's epithelium (Hess, 2002) and disruption of estrogen receptor 1 (ESR1) results in the formation of an increased number of blind ending tubules (Hess et al., 2000) and abnormal epithelial morphology (Hess et al., 1997b; Lee et al., 2009). Interestingly, loss of AR during perinatal development also produces abnormal rete testis and efferent ducts, similar to the loss of ESR1 alone (Rivas et al., 2002). Ciliated cells appear in the early postnatal period in mice and by day 28 in rats (Ilio and Hess, 1994). Differentiation of the conus epithelium is delayed until about day 32 in rats. In men, ductuli efferentes formation first begins at about 6 weeks of fetal development and lumen canalization begins during the eighth week, but complete formation within the head of the epididymis does not occur until between 20 and 28 weeks. Nonciliated cells begin to differentiate even in fetal life, as aquaporin-1 (AQP-1) is expressed in the apical brush border of the epithelium. Expression of other proteins and cellular organelles associated with nonciliated cell physiology begins as early as day 7 postnatally (see review: Hess, 2002), but lysosomes and a fully developed endocytic apparatus are not found until near early puberty.

A common developmental anomaly in efferent ducts is the formation of blind-ending tubules (Fig. 2), which are quite common in rodents. These abnormal tubules are also seen in larger mammals and man (Guttroff et al., 1992). The aberrant tubules can arise from many regions: directly from the rete testis, branching from any region of the efferent ductules and growing blindly from the epididymis. In larger mammals and man, blind-ending ducts are associated with sperm granulomas and epididymal cysts and thus contribute to infertility and pathology in the caput epididymis (Ilio and Hess, 1994). However, in the rodent aberrant tubules do not accumulate sperm or form granulomas, and the epithelium is underdeveloped and contains little cytoplasm, resulting in relatively small tubules that are surrounded by dense connective tissue.

Efferent Duct Epithelium

There is an abrupt change from the squamous to cuboidal/columnar epithelium at the histological junction of the rete testis and efferent ductules (Fig. 3), whose epithelium is composed of ciliated and nonciliated cells, with some species also showing basal cells and intraepithelial lymphocytes or macrophages (Hess, 2002). The efferent ductule epithelium sits on a typical basement membrane that is surrounded by a thin smooth muscle layer. There is considerable variation in cell morphology along the length of the ductules, as well as species variations (Ilio and Hess, 1994). Regional differences are principally the presence or absence of lysosomal granules, vacuoles and endocytic vesicles in nonciliated cells. It is unclear whether these morphological differences represent the same cell type in different phases of function or if the cells permanently express varying morphologies along the efferent ducts. In some regions, particularly proximal, the epithelium is fairly uniform, but in the conus and common duct areas there can be significant variations in epithelial height, with large folds occurring in some species such as in birds and man. In the rat, unique grooves penetrating nearly to the basement membrane can be found running longitudinally along sections of the ductal epithelium (Fig. 4), but they are inconsistent in location (Hess, 2002). These grooves are lacking in most species but are seen in some regions of human efferent ductules (Yeung et al., 1991). The transition from efferent ductule to initial segment of the epididymis is typically abrupt, as the epithelium suddenly changes from short columnar to tall, pseudostratified columnar cells with thin, branched microvilli (also called stereocilia). However, in humans, the transition appears to be gradual, with islands of epididymal cells first seen interspersed with efferent ductule epithelium (Yeung et al., 1991).

Ciliated Cells

A noteworthy characteristic found in efferent ductules is the presence of motile (kinetic) cilia (Fig. 5), an organelle also present in the female oviduct. Nonciliated cells are present in greater proportions in the proximal zone and numbers of ciliated cells are

Fig. 3 Rete testis to proximal efferent ductule transition. The image has been inverted in photoshop to emphasize the abrupt transition (*) of the squamous epithelium of rete testis into the columnar epithelium of efferent ductules. Bar = 40 μm .

Fig. 4 Rat efferent ductule cross sections stained with periodic acid/Schiff and hematoxylin to show the carbohydrate rich areas of endosomes and lysosomes that are involved in fluid reabsorption in nonciliated cells. Ciliated cell nuclei are located near the lumen. The cross section on the bottom shows an epithelial groove (*boxed area*), where adjacent epithelial cell membranes abruptly penetrate the epithelium (*arrow*) until nearly touching the basement membrane. Bar = 20 μm .

increased in zones nearest the epididymis, but is also species variable (Ilio and Hess, 1994). Ciliated cells can occupy up to 80% of the epithelium (Hess, 2015). Cilia extend as parallel finger-like structures from basal bodies into the lumen (Fig. 5) and bend together in the lower half, but are more random near their tips. Surprisingly, the cilia have a rotational twist and random beat, rather than a coordinated wave (Hess, 2015). It has been suggested that the cilia's primary function is to stir the luminal fluids to ensure homogeneous fluid reabsorption by nonciliated cells (Hess, 2003, 2015). Across all species, ciliated cells have a typical appearance, with an abundance of apical mitochondria to provide energy for the motile cilia. The nucleus of ciliated cells has a consistently apical position in the cytoplasm near the lumen in rodent and avian species, but in man and other large mammals nuclear position varies by region. The nuclear membrane often exhibits deep indentations (Fig. 5). The cell is also recognized by examining the apical cell surface with high resolution to observe a row of basal bodies that support the extended ciliary structures.

Fig. 5 Light microscopy (LM) with periodic acid/Schiff staining (PAS) and transmission electron microscopy (TEM) of the efferent duct epithelium. (A) LM of mouse epithelium illustrating the ciliated cells with motile cilia extending from a row of basal bodies. A nuclear membrane indentation can sometimes be observed with light microscopy. Nuclei of nonciliated cells are located in the basal cytoplasm. Bar = 10 μm. (B) TEM of rat epithelium illustrating both ciliated and nonciliated cells. The ciliated cell has prominent cilia protruding into the lumen between microvilli and resting on basal bodies and rootlets that extend into the apical cytoplasm. Numerous mitochondria reside under the basal bodies to provide energy for the motile cilia. Bar = 1 μm.

Nonciliated Cell

The major cell type lining the efferent ductule lumen is the nonciliated cell (Fig. 6), whose absorptive function is critical for efferent ductule function. Their reabsorption of luminal fluids increases the concentration of sperm several fold (Clulow et al., 1998). In most species, the ratio of nonciliated to ciliated cells is about 3–5:1, but in the common duct of rats, ciliated cells are increased. Only bulls have a greater proportion of ciliated cells. Nuclei of nonciliated cells are always located basally near the basement membrane and sometimes show considerable indentation of the nuclear membrane. Also consistent with the function of fluid reabsorption is the presence of a highly folded plasmalemma in the basal aspects of the cell. In some regions, at least in rats, large lipid droplets are observed along the basement membrane, but cryomicroscopy and special stains are usually required for visualization (Ilio and Hess, 1994).

The nonciliated cell is characterized by an apical brush border of microvilli that connect the lumen to its apical cytoplasm via a labyrinth of canaliculi, vesicles and apical tubules at the base of the microvilli. Ultrastructural features associated with endocytosis in this cell type reveal large dilated tubular elements between the bases of microvilli and tubular coated pits that extend into the apical cytoplasm. Time course studies of luminal tracers suggest that the apical tubules are part of the elaborate endocytic/lysosomal system (Hermo et al., 1994). Approximately 30% of the apical tubules are recycled back to the apical plasma membrane, but the remaining tubules are involved in the formation of endosomes, multivesicular bodies and finally secondary lysosomes. The endocytic apparatus in the apical cytoplasm of rats (Fig. 6) contains more endosomes and lysosomes than in mice (Hess, 2002). The endocytic apparatus is apparent in the apical cytoplasm with transmission electron microscopy, but with light microscopy it is best visualized using periodic acid/Schiff staining of the associated carbohydrates (Fig. 4). In all species, there are regional differences in staining characteristics, with the terminal zone (common duct in rodents) showing more intense staining for endocytic activity.

Nonciliated cells have two additional distinctive features that are frequently overlooked. First is the presence of apocrine secretion of the apical cytoplasm, which is usually region specific and present only in larger mammals and birds (Ilio and Hess, 1994; Hermo and Jacks, 2002). Secondly, similar to rete testis epithelium, nonciliated cells of efferent ductules also possess a primary cilium that protrudes like a finger into the lumen, above the row of short microvilli (Hess, 2015). Primary cilia have recently been promoted as organelles that help to coordinate cell signaling pathways (Satir et al., 2010). Although nothing is known about this organelle in the male reproductive tract, we can speculate that it has an important signaling activity related to luminal fluid flow and possibly sperm concentration. In kidney, bending of the primary cilium in the direction of fluid flow in proximal tubules is associated with calcium signaling. Changes in the ciliary length are associated with occlusions and the repair of renal tubules (Christensen et al., 2012) and thus also may be important for efferent duct function.

Fig. 6 Transmission electron microscopy (TEM) and light microscopy (LM) with periodic acid/Schiff staining (PAS) of the nonciliated cell in the efferent duct epithelium. (A) TEM of the mouse epithelium with several nonciliated cells showing a luminal brush border of microvilli. Apical tubules extend from the bottom of adjacent microvilli and are involved in endocytosis of luminal fluids through the endosomal/lysosomal apparatus. Long, thin mitochondria are scattered in the cytoplasm and the large nuclei are located near the basal lamina (basement membrane). Lateral plasma membranes are folded near the basal region. Bar = 1 μm . (B) LM of rat nonciliated cells stained with PAS. The microvillus border is less distinct than with TEM. An abundance of endosomes and lysosomes are present in the apical cytoplasm and are PAS+. In some cells, lipid droplets or vacuoles are present near the basement membrane. Bar = 10 μm .

Function of Efferent Ductules

Efferent ductules transport sperm from the rete testis to the epididymis in approximately 45 min in the rat. However, they are more than sperm conduits, as the major function of efferent ductules is a kidney-like reabsorption of luminal fluid, which increases sperm concentration 28-fold as they enter the epididymis (Hess et al., 1997b; Clulow et al., 1998). It is reported that between 50% and 96% of luminal fluids are removed in efferent ducts as sperm transit this region, with most reabsorption occurring in the proximal zone, soon after leaving the rete testis (Clulow et al., 1998; Hess 2002; Hansen et al., 2004). Fluid reabsorption involves multiple activities, including solute transport, passive water permeability, endocytosis and secretion (Hermo et al., 1994; Clulow et al., 1998; Hansen et al., 1999; Hess, 2002). The epithelium is considered to have leaky tight junctions, which allows rapid equilibration of ions between lumen and blood (Hansen et al., 1999). Some of the more important proteins involved include SLC9A3 (Na^+/H^+ exchanger-3), AQP1 and 9 (aquaporins), CAR2 (carbonic anhydrase 2), CFTR (cystic fibrosis transmembrane conductance regulator), and Na^+/K^+ ATPase (Ilio and Hess, 1992; Hansen et al., 1999; Lee et al., 2001; Leung et al., 2001; Joseph et al., 2010).

The endocytosis pathway depends upon an elaborate morphological network of microvilli, coated pits, apical tubules, endosomes and lysosomes (described above). It has been calculated that approximately 50%–90% of the total protein leaving the testis is reabsorbed in the efferent ductules (see review Hess, 2002). Endocytosis may also provide an alternative route for water movement, because the aquaporin-1 (AQP1) knockout mouse did not show fluid accumulation in the lumen comparable to the *Esr1* knockout mouse (Hess et al., 1997b; Zhou et al., 2001). Endocytosis of the sulfated glycoproteins SGP-1 and SGP-2, Sertoli cell secretory proteins found among the luminal macromolecules in efferent ducts, is a classic example of protein removal from luminal fluid by endocytosis. SGP-2 is also called clusterin and apolipoprotein J (Morales et al., 1996). These proteins are bound to sperm in rete testis fluid but released from the plasma membrane of sperm in the efferent ductal lumen.

Physiology of the efferent duct epithelium depends on the presence of Na^+/K^+ -ATPase along the basolateral membranes and a Na^+/H^+ exchanger (SLC9A3) in the apical microvillus membrane (Zhou et al., 2001), which is consistent with Na^+ transport in the kidney (Hansen et al., 1999). About 70% of the fluid reabsorption is dependent on the apical SLC9A3 exchanger, which is higher than that of the kidney. Na^+ transport across the basal membranes is coupled with the movement of other ions such as Cl^- and HCO_3^- (Clulow et al., 1998). In the proximal region, bicarbonate is secreted into the lumen but there is nearly complete reabsorption of bicarbonate in the distal common duct. Thus, efferent ducts have the highest luminal pH (see review Clulow et al., 1998). Overall, the fluid movement model involves active Na^+ transport, luminal flow-dependent reabsorption, adrenal-independent fluid flow, electroneutral ion flux and rapid isosmotic reabsorption that equilibrates with blood plasma (Hansen et al., 2004). Water movement from lumen to interstitium includes both paracellular and transcellular pathways, with differential regulation of water channels in efferent duct epithelial membranes (Oliveira et al., 2005; Ruz et al., 2006; Hermo and Smith, 2011).

Regulation of Efferent Ductule Function

Regulation of efferent ductal function is beginning to be understood, but like in the kidney, fluid reabsorption is under multiple mechanisms of control and thus complex. Basically, there is direct physiological control, as well as an integrated endocrine regulation of fluid reabsorption in efferent ductules. Na^+/H^+ exchange at the apical membrane is most important in regulation of fluid reabsorption (Clulow et al., 1998; Hansen et al., 1999), but molecules involved in this process are regulated by steroid hormone receptor activity. However, direct control of reabsorption is provided by the luminal flow rate, which allows for the fine tuning of fluid reabsorption and careful regulation of sperm concentrations entering the epididymis (Clulow et al., 1998). This flow-dependence may be associated with the presence of motile and primary cilia lining the ductal epithelium (Hess, 2002, 2015), as cAMP has been shown to abolish fluid reabsorption (Man et al., 2003).

Efferent duct epithelium expresses multiple steroid receptors (Hess et al., 2011). AR is present, similar to other regions of the male reproductive tract; however, AR is not the most abundant receptor. Instead, ESR1 is the predominant steroid receptor (Fig. 7) and is expressed in efferent ductules at levels higher than the female uterus (Hess et al., 1997a, 2011). Therefore, for many years it was assumed that 17 β -estradiol (E2), the natural ligand of ESR1 would be the predominant hormone required for regulating efferent duct function. However, such reasoning is incorrect. The steroid estrogen is not essential for efferent duct morphology and function, but its receptor, ESR1, is indispensable.

Esr1 knockout mice (*Esr1*KO) were infertile and showed dramatic rete testis dilation (Eddy et al., 1996), which was subsequently shown to result from the loss of ESR1 activity in the efferent duct epithelium (Hess et al., 1997b). In *Esr1*KO mice, efferent ducts were also distended with luminal fluids and epithelial height was reduced due to the loss of microvilli and endocytic apparatus. Accumulation of luminal fluids produced back pressure within the testis, resulting in dilation of rete testis and seminiferous tubules and long-term testicular atrophy, while androgen levels were elevated. Because the *Esr1*KO mouse was a developmental model, the receptor was also inactivated in adult males using a pure antiestrogen compound and results recapitulated the *Esr1*KO phenotype (Oliveira et al., 2002, 2003; Cho et al., 2003). Thus, blocking the estrogen receptor, without lowering androgens or removing estrogens, completely disrupted efferent duct physiology and morphology. Expression of many proteins involved in fluid reabsorption (SLC9A3, AQP1, 9, CAR2, SLC4A4, CFTR, SLC26a3, ATP1a1) are altered by the loss of ESR1 activity (Lee et al., 2001, 2008; Zhou et al., 2001; Toda et al., 2008; Joseph et al., 2010).

The *Esr1*KO mouse data clearly indicate that the receptor is required for efferent duct morphology and function; therefore, a similar response was expected following blockage of endogenous estrogen production. Aromatase, the enzyme that converts androgens to estrogens, was eliminated in aromatase knockout mice (ArKO), but the males were basically normal at first with an initial fertility and no evidence of fluid accumulation in the testis, although with aging there was a progressive disruption of spermatogenesis (Robertson et al., 2002). These data seemed inconsistent with the *Esr1*KO mouse and at first obfuscated our understanding of estrogen and efferent duct function. However, further studies showed that ESR1 expression is constitutive in efferent ducts and not reduced after castration or ductal ligation (Oliveira et al., 2004). E2, dihydrotestosterone (DHT) and 5- α -androstane-3- β -17- β -diol (a DHT metabolite) stimulated efferent ductal epithelium following castration-induced regression (Oliveira et al., 2004; Picciarelli-Lima et al., 2006). Thus, endocrine regulation of efferent ducts may involve both estrogen and androgen receptors, with or without the natural ligand in a ligand-independent manner or through the binding of a DHT metabolite or by the interaction of AR/ESR1 complexes with specific DNA response elements.

The only way to decrease efferent duct ESR1 has been to treat males with high doses of E2 or to block the receptor with a potent antiestrogen (Oliveira et al., 2003). However, it is interesting that perinatal treatment with the potent synthetic estrogen diethylstilbestrol (DES), with or without the blockade of androgen production, had no effect on ESR1, but did induce disappearance of AR, and resulted in abnormal rete testis and efferent ducts nearly identical to the *Esr1*KO mouse (Rivas et al., 2002). The DES study supports the hypothesis that androgen/estrogen balance, especially developmentally, may be important. Another study also

Fig. 7 Mouse efferent ductules immunostained for estrogen receptor, ESR1. Staining is intense in the nuclei of the epithelium. The ciliated cell nucleus appears to have somewhat lighter staining. Light staining is also seen in the cytoplasm. Bar = 20 μm .

suggested a role for AR and ESR1 interaction in the efferent ducts, as exogenous testosterone supplementation increased fluid reabsorption, but an anti-androgen (flutamide) and an anti-estrogen (tamoxifen) gave the same result, while E2 caused a decrease (Clulow et al., 1998). Unfortunately, these early studies did not examine changes in AR and ESR1 expression, making interpretation difficult, as E2 treatment alone downregulates ESR1 and AR (Oliveira et al., 2004). A recent study showing that membrane ESR1, in addition to nuclear presence of ESR1, is required for normal efferent duct morphology (Nanjappa et al., 2016) raises new questions regarding mechanisms that coordinate the regulation of this male reproductive tract region.

Conclusion

The efferent ductules provide an essential connection between the testis and epididymis and their normal function is required for male fertility. In numerous species, efferent ducts occupy a major portion of the head of the epididymis. This kidney-like organ displays a dynamic cellular morphology reflecting its major function in the reabsorption of over 90% of the luminal fluid, which results in a 28-fold increase in sperm concentration. The inaccessible location of these ductules, buried in thick connective tissue in larger mammals or the opaque epididymal fat pad in rodents, has resulted in their morphological and physiological contributions being easily overlooked. The epithelium has a unique presence of motile cilia, which function to stir the luminal fluids, but also primary cilia extending from the surface of nonciliated cells, possibly involved in the complex physiology associated with ion transport and water movement. Regulation of efferent ducts involves complex interactions of both androgens and estrogens, with and without natural ligands, and also requires the presence of at least the membrane estrogen receptor. An understanding of the mechanism of hormonal balance that is required for efferent duct function remains elusive, but it is well established that ESR1 expression is abundant in this region and it stays intact under multiple experimental conditions.

Glossary

Efferent ducts Delicate and small, coiled tubules, lined by an epithelium of ciliated and nonciliated cells that reabsorb over 95% of the luminal fluids and concentrate sperm that are transported from rete testis to the epididymis.

Funnel organization Efferent ductules found in rodents show this type of formation. Numerous individual ducts arising from the rete testis eventually merge until there is only one small tubule that enters the head of the epididymis, thus funneling all sperm into a more concentrated space.

Faslodex® A pure antiestrogen drug (ICI-182,780) that blocks estrogen binding to estrogen receptors and destabilizes the receptors leading to their degradation and preventing their nuclear transcriptional activation. This compound causes an increase in testosterone.

Granuloma An inflammatory reaction in a tissue, when there is an attempt to wall off the foreign substance. In rete testis and efferent ducts, the foreign substances are sperm, but also immature spermatids that can be sloughed into the seminiferous tubular lumen.

Parallel coils organization Efferent ductules found in larger mammals and man have this type of formation. Most of the numerous individual ducts arising from the rete testis do not merge, but eventually coil and then enter separately into the head of the epididymis.

Rete testis An irregularly-shaped chamber of anastomosing channels, lined by a cuboidal to squamous epithelium, extending from the tunica albuginea and connecting to the separate efferent ductules.

Spermatocele A cyst found in rete testis, efferent ductules or head of the epididymis, which retains a watery fluid and sperm. These can form as abnormal diverticula during development or after an inflammatory response.

Nomenclature

AR Androgen receptor

AQP1 and 9 Aquaporin 1 and 9

cAMP Cyclic adenosine monophosphate

Cftr Cystic fibrosis transmembrane conductance regulator

DES Diethylstilbestrol

DHT Dihydrotestosterone

ESR1 Estrogen receptor-1 (ER α)

*Esr1*KO Estrogen receptor-1 knockout

E2 17 β -estradiol

FGF8 Fetal growth factor-8

OPN Osteopontin

RTF Rete testis fluid

SLC9A3 Na⁺/H⁺ Exchanger-3

T Testosterone

VDR Vitamin D receptor

Endocrinology of Rete Testis and Efferent Ducts

Rete testis and efferent ductules are responsible for the transport of sperm from testis to the head of the epididymis. This transit route for sperm involves an important modification of the luminal fluids, primarily in efferent ductules, where over 95% of the fluid is reabsorbed, thus concentrating sperm prior to storage and maturation in the epididymis. Our knowledge of endocrine regulation of these two, sequential organ chambers has been limited due to the fact that most studies have emphasized the testis and epididymis and because it has been difficult to isolate and work specifically with the smaller and delicate tissues of rete testis and efferent ducts. There is no lack of steroid hormones in the luminal seminal fluids that arrive from seminiferous tubule secretions and steroid receptors are plentiful in both the rete testis and efferent duct epithelium, but direct evidence of functional regulation is found only for the efferent ducts, which appear to depend more on estrogen receptor- α (ESR1) than androgen receptor (AR), the

recognized male hormone receptor. Much of what we have learned has come indirectly from experimental models and various knockout mice, but a pattern has emerged suggesting that hormonal regulation of this region in the male reproductive tract depends on the balance of androgens to estrogens, rather than the specific concentration of either hormone alone, particularly during development.

Hormone Receptors

Androgen receptor (AR) is abundant throughout the male reproductive tract epithelium and is strongly expressed in rete testis and efferent ductules (Table 1). In contrast, reports of ESR1 expression have been inconsistent for rete testis, depending on species and age. On the other hand, ESR1 expression in efferent ductule epithelium has been very strong in all species studied and at all developmental stages. Data for the ciliated cells of the ductal epithelium have been inconsistent, with some being negative for ESR1 in some species and in others being weak to strongly positive. It is noteworthy that the nonciliated epithelial cells of efferent ductules express an abundance of several nuclear and cytoplasmic steroid receptors in the same cell (Fig. 1). However, the way in which multiple steroid receptors interact and sort their use of overlapping cofactors in the regulation of transcription remains to be determined. Nevertheless, the efferent ductule data highlight the importance of an androgen/estrogen balance in its physiology.

Regulation of Function

Fluid entering the rete testis from seminiferous tubules contains an abundance of steroid hormones and metabolites of both androgens and estrogens, as well as progesterone. Information regarding their direct regulation of adult rete testis function is lacking because most studies were focused on testicular effects, which were often determined by ligation of the proximal efferent ducts and collection of the accumulated fluids. Early studies reported large differences between seminiferous tubule fluid and rete testis fluid (RTF), but subsequent studies using better techniques found that sperm and inositol concentrations are similar in both regions, but differences in potassium, chloride and protein concentrations are significant and rete secretions provide some dilution to the luminal contents. Major changes in the luminal fluids occur in the efferent ductules, where sperm concentration is increased 28-fold. Treatment with LH does increase androgen concentration in RTF, but direct effects on rete testis are not known.

Table 1 Hormone receptors found in rete testis and the efferent duct epithelium

Receptor ^a	Rete testis	Efferent duct
AR	+++	+++
ESR1	+/-	++++
ESR2	++	++
PR	-	+/-
VDR	ND	++
THRA	ND	++
FSH-R	ND	+

^aAR: Androgen receptor; ESR1, 2: estrogen receptors α and β ; PR: progesterone receptor; VDR: vitamin D receptor; THRA: thyroid hormone receptor α ; FSH-R: follicle stimulating hormone receptor; ND: not determined.

Fig. 1 Immunohistochemical staining for nuclear steroid receptors located in the epithelium of hamster efferent ductules. (A) ESR1 (estrogen receptor- α) showing nuclear staining in both ciliated and nonciliated cells. (B) Androgen receptor (AR) is positive in both epithelial cell types. (C) Vitamin D receptor (VDR) is positive in all epithelial cell types but some ciliated cells are negative (blue nucleus). (D) Thyroid hormone receptor- α (THRA), is positive in all epithelial cell types. Bars = 10 μ m. Previously published by Hess, R.A., Fernandes, S.A., Gomes, G.R., Oliveira, C.A., Lazari, M.F. and Porto, C.S. (2011). Estrogen and its receptors in efferent ductules and epididymis. *Journal of Andrology* 32(6), 600–613 and used with permission.

Regulation of efferent ductule function has received more investigation, but the data paint a complex picture suggesting that multiple mechanisms are involved in the regulation of fluid reabsorption. Exogenous testosterone (T) treatment increased, but estradiol (E2) decreased fluid reabsorption in rat efferent ducts. Tamoxifen (an antiestrogen) and flutamide (antiandrogen) gave results similar to that of T. Testosterone in vitro also inhibits cAMP induced secretion of Cl^- , possibly working through a membrane receptor, and cAMP treatment alone inhibits overall fluid reabsorption. On the other hand, Faslodex[®] (a pure antiestrogen) treatment in the adult results in total blockage of fluid reabsorption and an upregulation of *Cfr*, which increases the movement of water into the lumen. Thus, it is possible that the estrogen pathway is responsible for the reabsorption, while T is responsible for the regulation of secretion, which provides a balance for the overall physiology that is proportional to hormonal concentrations found in the luminal fluids. Alterations in numerous transport-related genes have also been reported, as well as genes associated with extracellular matrix remodeling, which would account for the pathomorphological changes seen in efferent ductules of the *Esr1* knockout mouse (*Esr1KO*). In the *Esr1KO* mouse and Faslodex[®]-treated rodents, *ESR1* is lost but *AR* remains expressed. These data appear to be contradictory at times, but new studies have provided an explanation and emphasize the importance of determining the effects of treatment on the expression of steroid hormone receptors in these tissues, which was lacking in the earlier studies. In efferent ducts, exogenous administration of E2 causes the loss of both *AR* and *ESR1*, while T, as well as dihydrotestosterone (DHT), has no effect on either receptor. Thus, the interpretation of prior physiological studies must be reexamined, especially in light of data from the *Esr1KO* and adult males treated with Faslodex[®], which demonstrated that blocking the estrogen receptor alone, without altering T was sufficient to disrupt the primary physiological function of efferent ductules, reabsorption of over 95% of the luminal fluid.

ESR1 expression is constitutive in efferent duct epithelium and is undisturbed by castration or ligation at the rete testis junction. However, castration and ligation decreased the luminal diameter (due to the loss of rete testis fluids) and reduced epithelial height, even with *ESR1* expression. After castration, *AR* expression was lost. Treatment after castration with E2, T or DHT increased the epithelial height but not to normal levels. The best response was with the combined treatment of E2 and T. Some genes expressed in efferent ductules contain both estrogen and androgen response elements. For example, *Slc9a3* message (the Na^+/H^+ exchanger) was reduced nearly sixfold in *Esr1KO* and antiestrogen-treated mice, but in castrated males, T increased the expression. *SLC9A3* is located along the microvillus border of nonciliated cells and is the major protein responsible for fluid reabsorption. Thus, the complexity of efferent ductule regulation likely requires dual involvement of androgens and estrogens for growth and maintenance of epithelial cell morphology and the physiology of reabsorption and secretion. However, future studies are necessary if we are to uncover the separate, as well as overlapping transcriptional activities in these unique ductules.

One clear example of dual regulation by estrogens and androgens was found in the regulation of aquaporin 9 (AQP9) expression in the microvillus border of the nonciliated cells. Castration, as well as ligation, caused the down-regulation of AQP9 in both efferent ductules and the initial segment epididymis. DHT, but not T, was able to restore AQP9 expression in both efferent ductules and initial segment region. E2 alone, as well as 5α -androstane- 3β - 17β -diol, also restored AQP9 immunostaining in the efferent ducts but not in the epididymis. The antiestrogen Faslodex[®] produced a dramatic reduction in AQP9, without any effect on efferent ductule expression of the *AR*. Therefore, a differential regulation of AQP9 expression was seen in efferent ductules and the epididymis, but only in the efferent ducts was its regulation dependent on both *AR* and *ESR1*. Careful interpretation of these studies is required, as it has been shown that Faslodex[®] also decreases AQP1 expression in efferent ductules. However, with AQP1 it has been demonstrated that its disappearance is secondary, due to the morphological disruption of microvilli, while AQP9 downregulation occurs prior to the loss of the microvillus border. Osteopontin (OPN) is another protein that shows differential regulation between efferent ductules and epididymis. After castration, OPN is lost in the epididymis, but shows no change in the efferent duct epithelium. Unfortunately, the expression of VDR, a known regulator of OPN, was not evaluated, but it is possible that VDR expression is constitutive in efferent ducts, similar to *ESR1*, or that a dual regulation of OPN is provided by the two respective hormones.

The aromatase knockout mouse (*ArKO*) showed no effects on the efferent ductule epithelium and raised questions regarding the claim that estrogen was essential for male reproduction. However, there is continuous expression of *ESR1* in the *ArKO*, as seen after castration; therefore, efferent duct morphology and function is *ESR1* dependent, but may not require direct E2 binding. This conclusion has become more complex with the discovery that loss of the membrane *ESR1*, while retaining nuclear *ESR1*, produces the same efferent duct phenotype as seen in the global *Esr1KO*. These data suggest that the ligand-independent activation of *ESR1* may be important in the efferent duct epithelium, but also dependent on the ability of the membrane *ESR1* to coordinate the nuclear signaling required for fluid reabsorption, which also is known to be reliant on flow dynamics of the luminal fluids.

Pathology of Rete Testis and Efferent Ducts

A much greater understanding of rete testis and efferent ductule physiology has been gathered by the study of pathological lesions. Basically, there are three major ways to induce abnormalities in this region of the male reproductive tract (Fig. 2): (1) physical ligation; (2) luminal compaction or excessive reabsorption; and (3) inhibition of reabsorption. One of the earliest discoveries was that ligation of the efferent ductules leads to the accumulation of fluid from the seminiferous tubules, resulting in dilation of the lumen in both efferent ductules and rete testis. If the ligation is placed near the rete testis, fluid accumulates also in the testis, causing dilation of the tubules, increased testis weight and eventually testicular atrophy, which is called “back pressure atrophy.” A broad range of direct and indirect effects that involve rete testis and efferent ductule dysfunctions is listed and discussed in Table 2.

Fig. 2 The drawings represent three basic mechanisms that lead to efferent duct pathological responses: ligation, compaction, and inhibited reabsorption. Histological representations are shown above each drawing. (A) Rete testis dilation (double arrow) and excessive buildup of fluid occurs rapidly following ligation of efferent ductules, occlusions of any kind near the rete testis and inhibition of fluid reabsorption. After ligation, the resorption of Na^+ and H_2O and secretion of Cl^- remain normal but the fluid produced by seminiferous tubules exceeds the physiological limit and begins to accumulate. If the dilation continues unresolved for an extended period of time, seminiferous tubules also dilate and the testis shows a temporary increase in weight. The long-term consequence of rete dilation is seminiferous tubular atrophy (St), with the loss of the germinal epithelium. (B) Efferent ductule occlusion occurs following compaction of the luminal contents (double arrow). The center photo is from a rat treated with the fungicide benomyl, which induces sloughing of immature spermatids along with normal sperm that become compacted in the lumen of efferent ducts (*), due to the excess removal of water and other noncellular components, which produces ductal occlusion. Within hours of treatment, an inflammatory response of massive numbers of neutrophils (polymorphonuclear leukocytes) can be seen surrounding the ductal basement membrane, in an effort to ward off the luminal contents that are antigenic. It is not known if the inflammatory response caused an increased reabsorption of fluid or decreased epithelial secretion, but the end result is an occlusion, which eventually can lead to calcification, fibrosis, and scarring. Under certain conditions, the epithelium may enter mitosis and attempt to re-canal or grow around the occluded area. (C) Efferent ductule dilation (double arrow) occurs following the inhibition of fluid reabsorption and/or excessive secretion into the lumen, as well as blockage downstream near the common duct and initial segment epididymis. Inhibited reabsorption occurs in the *Esr1*KO mouse and following adult exposures to the antiestrogen Faslodex, and involves the downregulation of water channels and ion transport proteins, as well as the upregulation of *Cfr*, which results in the movement of water from the interstitial space into the lumen (Lu). This figure is modified from Hess, R.A. (2014). Disruption of estrogen receptor signaling and similar pathways in the efferent ductules and initial segments of the epididymis. *Spermatogenesis* 4(2), e979103, available online at <http://www.tandfonline.com/doi/full/10.4161/21565562.2014.979103>.

Developmental Pathology

Embryological development is a separate event for rete testis and efferent ductules, until they eventually join in the extratesticular region. Thus, developmental anomalies can result in separate pathological defects, but after the two organs join to form a patent lumen for the passage of sperm, lesions can begin to overlap. It has been shown that kidney malformations can be associated with efferent duct abnormalities, because there are specific genes associated with the formation of kidney proximal tubules (metanephros origin) that are also specific for the developing efferent ducts (mesonephros origin). However, it can be difficult to make interpretations when the rete testis shows cystic formations, because the cause could be the abnormal development of efferent ducts and subsequent luminal obstruction. There are several hormones and specific genes that are essential for normal development of efferent ductules. For example, loss of FGF8 (fetal growth factor-8) results in the failure to form efferent ductules and the *Lgr4* knockout results in less convoluted ducts. Both of these mutant abnormalities result in male infertility.

The effects of diethylstilbestrol (DES) exposure on male reproductive tract development are considered classical examples of estrogen-included developmental disorders. They include cryptorchidism, testicular atrophy, epididymal cysts, sperm abnormalities, sperm granulomas, adenocarcinoma, prostatic inflammation, and other changes that could affect fertility and male reproductive function. Of particular note, DES causes the formation of rete testis adenocarcinomas, luminal dilation of both rete testis and efferent ductules and significant reduction in epithelial cell height. These changes were first thought to be due to an early induction of estrogen receptor in the male tract, but further studies are now pointing to disruption in the androgen/estrogen balance, both in the hormones and their respective receptors.

Table 2 Direct and indirect lesions associated with dysfunctions of rete testis and the efferent ductules

<i>Lesion</i>	<i>Discussion</i>
Inflammation	It is not known if this is a cause or the result of ductal abnormalities; however, neutrophils induce considerable epithelial damage. Inflammatory cells can also enter the lumen and have been associated with sperm stasis and blockage of efferent ducts
Ductal occlusion	Causes may involve: (a) compaction due to excessive reabsorption; (b) epithelial necrosis; (c) luminal calcification; (d) varicocele vascular dilation; (e) blind-ending formations
Phagocytosis	This appears to be an epithelial response to sperm stagnation
Sperm granuloma	Formed in response to sperm stasis, ductal occlusion and inflammation and in larger mammals
Spermatocoele (cyst formation)	This may begin due to a developmental diverticulum of the rete testis or an overgrowth of the epithelium
Fibrosis	This is typically an end-stage result of overproduction of collagen in response to sperm stasis, inflammation and necrosis of the efferent ductule epithelium
Luminal calcification (lithiasis)	Unknown cause, but may involve osteopontin expression in efferent duct epithelium and an imbalance in ESR1 and/or VDR. In rete testis, these could be derived from microlithiasis granules in the seminiferous tubules
Epithelial hyperplasia	This can occur developmentally in the rete testis as a cystic overgrowth or cribriform pockets in the epithelium. It is also seen in efferent ductules after long-term occlusion, specific gene knockouts and in particular epididymal cystadenomas in men
Recanalization	This is a term used to describe growth of the efferent duct epithelium in an attempt to circumvent the luminal occlusion
Ciliary loss	Knockout of genes associated with cilia formation can result in the disruption of fluid reabsorption. It is unclear if the disruption is primary due to failure of fluid mixing or secondary due to indirect effects on the nonciliated cell
Desquamation	Certain toxicants cause necrosis of the epithelium; however, this can be secondary to the disruption in area blood flow
Lipid accumulation	Changes in cytoplasmic lipid vacuoles has been noted in some pathological conditions, but it is not known if this is the cause or a secondary accumulation due to disruption in the endocytosis/lysosomal pathways
Efferent duct luminal dilation	Inhibition of fluid reabsorption will cause dilation in rodent species. Occlusions only in the distal duct will cause dilation in the proximal ducts. Abnormal development of the ductal epithelium will show luminal dilation during the postnatal period
Rete testis luminal dilation	This is a classic or signature response due to efferent duct occlusion in all species, but also a response due to inhibited fluid reabsorption in the rodent species. It may be difficult to separate fluid accumulated induction of dilation from overgrowth, if the lesion has been present from birth. Rete dilation can also occur independent of efferent duct dysfunction in cases of blind-ending rete testis cyst formation
Testicular swelling	This accumulation of fluid occurs only if rete testis fluid cannot exit through the efferent ductules at a required rate of flow. It is caused by ductal occlusion near the rete testis or failure of reabsorption
Seminiferous tubular atrophy	There can be many causes of testicular atrophy that are independent of rete testis and efferent ductule function. However, sustained failure of adequate fluid exit through the rete testis can induce “back-pressure atrophy.” There are species differences in response and it appears the cranial seminiferous tubules are more susceptible to this pathology than are the tubules in the caudal region of the testis

Prenatal exposure to DES has no effect on ESR1, but instead causes the disappearance of AR, which then results in abnormalities in the rete testis and efferent ducts. However, treating with both DES and T did not fully restore the efferent duct lumen, but did restore the rete testis to normal diameter. DES also abolished AQP1 expression in the developing efferent ductal epithelium, but a GnRH antagonist (which would block the stimulation of Leydig cell production of T) produced no change in AQP1. These data are confusing when we consider the *Esr1*KO mouse, in which there is no effect on AR, but ESR1 is lacking in efferent ductules, and the phenotype is nearly identical to that produced by DES. The only conclusion that can be made is that during development a careful balance in the androgen/estrogen pathways is required and that both hormones overlap in as yet unexplained ways.

Adult Pathology

A large number of chemicals have been shown to induce rete testis and efferent ductal abnormalities in the adult male. Some lesions are direct causes of exposure, but sometimes it is difficult to be sure, as they may be indirect effects (Table 2). For example, excessive reabsorption of fluid may induce rete testis dilation but the same lesion is caused also by the inhibition of fluid reabsorption. The reabsorption of fluid at an excessive rate can leave the lumen compacted with sperm, clogging the exit and occluding the efferent ducts. If the occlusion occurs in the proximal efferent ducts, such pathology will also obstruct the rete testis, if the cause is not resolved rapidly. This pathologic response is most susceptible in rodent species that have the funnel organization of efferent ductules. Exposure to the fungicide benomyl, a microtubule poison, illustrates this pathological response (Fig. 2). Benomyl causes massive sloughing of germ cells from the seminiferous epithelium, but sloughing alone does not induce occlusions. Instead, excess removal of luminal fluid concentrates the cellular components, with as yet an unknown mechanism. However, one potential mechanism may involve an inflammatory response, as rapid recruitment of neutrophils has been noted in several cases of toxicant-induced occlusions and granuloma formations in efferent ducts and rete testis. For example, it is known that the tight junctions

Fig. 3 An example of sperm granuloma formation adjacent to a normal patent efferent ductule. The lumen (Lu) is clear with cilia extending into the opening in the normal ducts, as few sperm are present in the ductules, until after fluid reabsorption. The occluded ducts are surrounded by thick layers of inflammatory cells, some of which have penetrated the epithelium. The lumen (Lu) has become compacted and the epithelium appears nearly destroyed by the process of forming the sperm granuloma. Bar = 100 μ m.

are leaky in this region of the male tract and in experimental allergic orchitis, inflammatory lesions are observed first in the rete testis. A wide range of chemicals induce occlusions, as well as a growing number of gene disruption models. In most cases, it appears that either a direct alteration in fluid reabsorption has occurred or there has been an induced leakage of sperm antigens from the lumen, which causes inflammation and eventually the formation of the granulomas (Fig. 3).

Dilation due to reabsorption failure in rete testis and efferent ducts is opposite to that of occlusion. The responses to both dilation and occlusion are now recognized as classical or signature lesions, in the sense that if blockage occurs near the rete testis, with lumens greatly expanded by excess fluid, the sequella will include a temporary increase in testis weight, seminiferous tubular dilation and subsequent atrophy. The primary cause of luminal dilation is the failure to reabsorb fluids at a required rate, particularly in the rodent species. The resulting excess fluid overwhelms the funnel organization found in the terminal segment of the efferent ducts. Species having numerous parallel coils of ductules entering independently into the epididymis have not shown this typical response, although individual ductules can show dilation, as well as regions of the rete testis. ESR1 expression is an absolute requirement for fluid reabsorption in efferent ductules, with or without the presence of E2 produced by aromatase activity. The pathological response to ESR1 loss or interference with its transactivation is a dramatic dilation of ductal lumens and loss of epithelial organelles required for fluid reabsorption, which also results in a dramatic decrease in epithelial height. This response is found early during development in the *Esr1* KO, but treatment of adult wild-type males with the potent antiestrogen Faslodex[®], and other chemicals that target ESR1, also result in a nearly identical pathology. Other causes of this pathological response include disruption of ciliary formation, loss of the sodium/hydrogen exchanger, carbonic anhydrase II, polycystin-1 and vasodilation of blood vessels near the rete testis.

Pathology in Men

There are numerous reports of rete testis and efferent ductule pathologies in men. It has been stated that 1/3 of human epididymides show evidence of one or more efferent ductules being occluded and pathological changes are more common in efferent ducts than in the epididymis and vas deferens. These reports primarily deal with various types of cyst formations, with several variations on this theme, including the following: cystadenoma, cystic ectasia, cystic dysplasia, congenital blind-ends, and spermatocele. These cysts can be associated with inflammation, as well as efferent duct occlusions, but in some cases the exit of sperm into the epididymis remains intact. At least five human diseases have been associated with abnormal functions of efferent ducts and rete testis due to developmental defects. These diseases include: von Hippel-Lindau disease, Young's syndrome, varicocele (dilated pampiniform veins), cystic fibrosis, and kidney disease or renal failure.

Conclusions

Pathological changes in rete testis and the efferent ductules are commonly associated with the endocrine regulation of these tubular organs. The complexity of these pathological changes appears to involve a disruption in the delicate balance between androgen and

estrogen signaling pathways, in an epithelium that expresses multiple nuclear steroid receptors in the same cell. The intricate coordination of this endocrinology is further complicated by the presence of kinetic ciliated cells in the efferent ducts and primary cilia in both the rete testis and efferent ducts. An understanding of the mechanisms required for maintenance of the hormonal balance will help to establish the primary versus secondary causes of reproductive pathology in this region of the male reproductive tract.

Glossary

Apocrine secretion Secretion of cellular components (e.g., proteins, peptides, nucleic acids) through blebbing of the apical membrane of cells and the subsequent release of membrane-bound vesicles into the lumen.

Blood–epididymis barrier Physical barrier formed at the apical pole of the epithelium of the epididymis to prevent equilibration between blood and epididymal fluid. This barrier maintains the unique composition of the latter that is important for sperm maturation and protection.

Epididymal fluid Fluid that bathes spermatozoa during their maturation in the epididymis. The composition of this fluid varies along the epididymal tubule as a result of strong secretion/reabsorption activities.

Epididymal sperm Spermatozoa that are found in the epididymis. Those entering the epididymis are immotile and unable to fertilize, while those stored in the distal region of the epididymis possess all the abilities required to fertilize an oocyte.

Epididymis A single convoluted tubule that transports spermatozoa from the testis to the *vas deferens*. This organ is responsible for the transport, maturation, and storage of spermatozoa.

Merocrine secretion The most common secretion pathway. Intracellular membrane-bound vesicles are carried to the cell membrane, and their contents (e.g., proteins) are secreted into the extracellular environment following the transient fusion of secretory vesicles with the outer cell membrane.

Posttesticular sperm maturation The process during which immature spermatozoa (i.e., nonmotile and devoid of fertilizing ability) acquire their capacity to move, to recognize and fertilize an oocyte. This occurs in the epididymis.

Evolution of the Epididymis in Vertebrates

The epididymis, from Greek *epi* for “on” and *-didymoi* for “twins” or “testicles,” is derived from the Wolffian duct. It connects the *rete testis* via multiple *vas efferens*, to the *vas deferens*. It is the hallmark of vertebrate phyla practicing internal fertilization such as cartilaginous fishes (elasmobranchs), reptiles, birds, and mammals. In species with scrotal testicles, the epididymis is located on the gonad surface whereas in species with inguinal or abdominal gonads, the distal portion of the epididymis with sperm storage functions is located more externally. In vertebrate phyla practicing external fertilization such as amphibians and teleostean fishes, the epididymis is not part of the male reproductive tract. In these species, fully functional spermatozoa are transported from the testis to the exterior via the spermatic duct (Jones, 2002).

In vertebrate species practicing internal fertilization, testicular sperm, even though fully differentiated, are nonfunctional and must transit the epididymis to acquire their fertilizing ability and forward motility. In these species, sperm release is not always synchronized with ovulation. It can be speculated that the epididymis generates heterogeneity among spermatozoa in such a way that subpopulations of male gametes deposited in the female genital tract will be functional at different time points in order to increase the fertility window of a given ejaculate.

Epididymis Anatomy

The epididymis is a long single highly convoluted tubule. The unraveled epididymal duct can reach a length of 50–60 m in large mammalian species and 3–5 m in humans. Sperm transit along the epididymis takes 3–12 days depending on the species and the length of the tubule. The diameter of the intraluminal compartment of the epididymis increases from the proximal to the distal region and the sperm concentration (spermatocrit) increases dramatically along the epididymis. Indeed, water reabsorption is one function performed by the epithelium bordering the intraluminal compartment of the epididymis and results in an increase in sperm concentration.

Based on gross anatomy, the epididymis is divided into three segments; the proximal caput (the head); an elongated middle corpus region and a distal, swollen cauda (Fig. 1). An additional proximal segment can be distinguished in rodent epididymis called the initial segment. Histology of the latter is characterized by epithelial cells with a cuboidal appearance when compared to the epithelial cells bordering the lumen of the caput epididymal segment. In large mammals and humans, the initial segment is not distinguishable. In fact, the proximal epididymal segment of the human epididymis is mainly formed by *vas efferens*. With regard to the male reproductive tract in general, the anatomy of the epididymis varies from one species to another (Yeung and Cooper, 2002; Sullivan and Mieusset, 2016). The abdominal, inguinal, and scrotal location of the testis also has an influence on the anatomy of the epididymis (Kleisner et al., 2010).

Fig. 1 The human epididymis. A photograph (*left*) and a longitudinal section together with cross sections (*right*) of a human epididymis. *Right panel* reproduces with permission from Sullivan, R., Belleannee, C. (2017). Role of the epididymis in sperm maturation. In de Jonge, C. J. and Barratt, C.L.R. (eds). *The sperm cell. Production, maturation, fertilization, regeneration*, 2nd edn. Cambridge: Cambridge University Press.

Connective tissue septa that separate the epididymis into segments have been described in laboratory rodents as well as in a limited number of species such as dogs and primates. These structures are constant from one individual to another and as such the epididymis can be divided into a fixed number of segments: 10 in the mouse and 19 in rats. It has been hypothesized that each of these segments responds differently to lumicrine factors controlling gene expression along the epididymis. In other mammalian species, including man, these connective tissues are not as well organized. Additional experimental work is necessary to understand the functionality of epididymal segmentation by connective tissue septa that has been described in some species (Turner et al., 2003).

Roles of the Epididymis: An Overview

With its location between the *rete testis* and the *vas deferens*, the epididymis is involved in *sperm transport* along the male reproductive tract. As testicular and epididymal spermatozoa are immotile, sperm transport depends on peristaltic movement of the epididymal tubule. Contraction of smooth muscle layers surrounding the tubule is also involved. Epididymal smooth muscle layers surrounding the epididymal tubule in the cauda segment and around the *vas deferens* are developed in humans and are involved in sperm progression at ejaculation.

As evidenced by pioneering studies performed on different mammalian species, the epididymis is of major importance to male fertility. Although spermatozoa collected from the caput epididymis are fully differentiated, they are immotile and unable to fertilize the egg (Orgebin-Crist, 1967). In vitro fertilization and artificial insemination performed with epididymal spermatozoa showed that sperm functionality increases during epididymal transit; the first sperm capable of fertilization appear in the corpus segment. Acquisition of both motility and fertilizing ability by spermatozoa transiting along the epididymis is collectively known as *sperm maturation*. Due to the extreme compaction of their DNA and the absence of many organelles such as Golgi/endoplasmic reticulum and ribosomes, spermatozoa leaving the testis are transcriptionally, and translationally inactive cells. Thus, they are incapable of controlling their own protein neosynthesis and function. Therefore, posttesticular sperm maturation exclusively depends on extracellular factors secreted by the epithelial cells surrounding the intraluminal compartment of the epididymis (Fig. 2). Proteins synthesized by the epididymal epithelium and secreted into the intraluminal milieu are essential for sperm maturation (Cornwall, 2009). Transcriptional as well translational activity of the epididymis are under androgen control: testosterone is secreted by the testis and dihydrotestosterone is synthesized locally through high epididymal alpha-reductase activity (Robaire and Hamzeh, 2011).

Fig. 2 Schematic diagram of the gross anatomy and the cellular organization of the epididymal epithelium.

Tight junctions between epithelial cells of the epididymal tubules allow maintenance of an *intraluminal milieu* that is distinct from other body fluids. In comparison to composition of the blood, the epididymal fluid calcium concentration is markedly lower, and phosphate and potassium concentrations are increased whereas sodium is decreased. The pH is acidic (pH around 6.5) and the osmolality is much higher than arterial blood. This peculiar inorganic salt composition of the epididymal fluid may contribute to dehydration of spermatozoa during epididymal transit. The tight junctions between epididymal epithelial cells form the *blood–epididymal barrier*, which, together with the blood–testis barrier, protect sperm against the immune system (Cyr et al., 2007). Spermatogenesis and the presence of sperm in the male reproductive tract occur long after the establishment of the immune defense of an individual. Tight junctions along the male reproductive tract ensure that the spermatozoa harboring specific autoantigens are isolated from the immune system. Together with this physical barrier, other factors are involved in the rather complex immune regulatory processes of the epididymis.

The distal cauda segment of the epididymis has a bulbous appearance. Compared to the upper epididymal segments, the thickness of the epithelium is reduced and the lumen diameter is greatly increased. The thinness of the epididymal epithelium in this segment correlates with low protein synthesis and secretory activities. In fact, the transcriptome of the cauda region reveals a much less complex gene expression pattern when compared to the caput and corpus epididymides. Whereas luminal secretions from caput and corpus epididymides are required for the acquisition of sperm motility and fertilizing ability, cauda epididymal secretions are important for the associated *sperm reservoir function*. The cauda epididymis has evolved to ensure that a sufficient number of spermatozoa will be available at ejaculation. The demand for sperm storage obviously depends on the reproductive behavior of each species. With respect to testis size, the cauda epididymis sperm reservoir capacity is important in species practicing polygynous or multimale/multifemale mating systems when compared to a monogamous species. In humans, the sperm reservoir capacity of the cauda epididymidis is estimated at 2–3 ejaculates; it can be as high as 10–15 ejaculates in large domestic animals. Experimental cryptorchidism in which the testis and/or the epididymis is relocated in the inguinal canal or in the abdominal cavity, clearly demonstrates that the cauda epididymis, and thus the sperm reservoir function, is markedly affected by temperature increase. From these observations, it was hypothesized that the cauda epididymis was the driving force for testicular descent. Once ejaculated, spermatozoa will survive 24–36 h in a physiological solution. In the cauda epididymis, these cells can survive up to 15 days. The sperm storage capacity of the cauda epididymis involves maintenance of sperm metabolic quiescence by preserving a low intraluminal pH and sodium concentration and a high fluid viscosity to inhibit flagellar motility. This is coupled with secretion of factors that inhibit sperm activation and capacitation. At ejaculation, these inhibitory factors are diluted allowing sperm activation (Bedford, 2015).

The epididymal functions of sperm transport, protection, maturation, and storage are complex. They depend on intricate interactions between the epididymal epithelium bordering the intraluminal compartment with lumicrine factors originating from the testis or from more proximal segments of the duct and/or with transiting spermatozoa. Epithelial cell populations found

in the epididymis exhibit specific gene expression patterns and exert independent functions to ensure proper posttesticular sperm processing in this organ. However, as evidenced by ex vivo/in vivo studies performed on whole epididymal tubules, epithelial cells also participate in a well-orchestrated intercellular communication system (Cornwall, 2009).

It is obvious that defects in these complex cell biology processes can impact male fertility even though the implication of the epididymis in the pathophysiology of sterility or infertility in males has been poorly investigated. On the other hand, these processes have been proposed as targets for novel male contraceptive strategies.

Despite its apparently simple organization, the epididymal epithelium is composed of different cell types that intercommunicate with each other (Fig. 2). This well-orchestrated cell organization is essential for optimal control of the sperm environment and epididymal functions. In the following sections, we will (i) portray the overall features of the epididymal epithelium, (ii) describe the unique features of each of the main cell types found in the epididymis, and (iii) summarize the principal functions ensured by each of these epididymal cell types.

Overall Features of the Epididymal Epithelium

The epididymis is formed by a two-layered pseudostratified epithelium (Fig. 2). The base of the epithelium is separated from the connective tissue by a basement membrane formed by a fibrous extracellular matrix. Smooth muscle and blood vessel endothelial cells populate the connective tissue. The apical pole of the epithelium is in direct contact with the sperm-bathing epididymal fluid and exposes microvilli, whose cytoskeleton is composed of actin filaments (as opposed to true stereocilia, which are microtubule-based structures). The composition of the intraluminal epididymal fluid is unique in terms of protein/ion content and, pH/osmolality parameters, and is important for sperm maturation. The presence of tight junctions between epididymal epithelial cells forms a blood–epididymis barrier, which controls this sperm-surrounding environment and discriminates it from blood. This junctional complex encompasses gap junctions that ensure communication and coordination between cells throughout the entire length of the epididymal tubule (Hermo and Robaire, 2002).

Epididymal Epithelial Cell Structures

Seven distinct cell populations are found in the different segments of the epididymis. While *clear cells* are found in the caput, corpus and cauda epididymidis, *narrow* and *apical cells* are exclusively present in the initial segment. *Principal cells*, which represent up to 80% of total epithelial cells, *basal cells*, *halo cells*, and *dendritic cells* are found along the entire tubule (Belleannee et al., 2012).

Principal cells

Principal cells are the major cell type found in the epididymis and exhibit a tall columnar shape in the proximal regions that transitions to a squared-off appearance in the distal regions. Principal cells are composed of efficient secretory and endocytic apparatus including endoplasmic reticulum, Golgi apparatus and secretory granules as well as coated pits, endosomes, multivesicular bodies, and lysosomes. The apical pole membrane of principal cells forms elongated microvilli that increase the surface area for exchange between epithelial cells and the epididymal fluid by up to 25 times. Principal cell microvilli measure on average 500 nm–1.0 μ m in length and 100 nm in width and are packed on the cell surface in large numbers to form the epididymal brush border (Hermo, 1995). This brush border allows for intraluminal components to be absorbed at a faster rate into principal cells through specific transporters. For instance, principal cells specifically express several channels and transporters such as: cystic fibrosis transmembrane conductance regulator (CFTR), aquaporin 9 (AQP9), bradykinin type 2 receptor, pannexins, chloride channel protein 3 (ClC3), membrane-associated carbonic anhydrases CAIV and CAII, and TRPV6 and TMEM16A that mediate the transport of elements important to epididymal physiology (i.e., ATP, chloride, calcium, water, and bicarbonate).

Epithelial principal cells are specialized in fluid secretion. At least three types of secretion exist in the epididymis: (1) secretion/reabsorption of ions, organic compounds, and water through transporters located at the apical pole of the cells, (2) merocrine, and (3) apocrine secretions. (1) *Secretion/reabsorption through transporters*. Epithelial cells lining the epididymis express transporters responsible for considerable changes to fluid composition throughout the epididymis. These changes include net water, Na^+ , Cl^- , and HCO_3^- reabsorption, K^+ secretion, carnitine secretion, and luminal acidification through aquaporins (water transporters), the $\text{Na}^+-\text{K}^+-2\text{Cl}^-$ cotransporter (NKCC1), cystic fibrosis transmembrane conductance regulator (CFTR, Cl^- , and HCO_3^- conducting ion channel), the organic cation/carnitine transporter (OCTN2), the Na^+/H^+ exchanger (NHE3), and the $\text{Cl}^-/\text{HCO}_3^-$ exchanger (AE2). These secretions into the lumen of the epididymis occur under the control of adrenergic and purinergic agonists and peptide hormones. (2) *Merocrine secretion*. Epididymal principal cells possess an extensive Golgi apparatus, which ensures the secretion of diverse glycoproteins tagged with a signal peptide through the classical merocrine secretion pathway. Exhaustive proteomic studies have shown that secretion/reabsorption of proteins is dynamic along the epididymal tubule and thereby creates distinct microenvironments in which spermatozoa sequentially acquire their fertilizing abilities. (3) *Apocrine secretion*. Apocrine secretion consists of the budding of the apical membrane of principal cells. Once released into the intraluminal environment, these blebs containing selected intracellular organelles of epithelial cells release small membranous vesicles referred to as epididymosomes (Machtinger et al., 2016) (Fig. 2). These extracellular vesicles play a role in the transfer of proteins to the sperm surface, including proteins necessary for sperm functionality such as those involved in recognition of the egg zona pellucida. Recent evidence shows that epididymosomes also transport small noncoding RNA as a mechanism of intercellular communication that can modulate gene expression along the epididymis (Sullivan and Saez, 2013).

Narrow cells

Narrow cells are only present in the initial segment of the adult epididymis in rodents. Their name refers to their characteristic elongated and narrow shape. As evidenced by electron microscopic studies, narrow cells contain numerous vesicles participating in endocytosis that are recycled to the apical plasma membrane, as well as numerous mitochondria. These cells express the proton pump V-ATPase subunits and are involved in proton secretion and acidification of the epididymal fluid in the rodent initial segments.

Apical cells

Similar to narrow cells, apical cells are found in the initial segment of the epididymis. Compared to other epididymal epithelial cells, apical cells display a spherical nucleus that is located at the apical pole of the epithelium. To date there is no evidence that these cells are in physical contact with the basal membrane of the epithelium. The fact that apical cells secrete regulated on activation, normal T cell expressed, and secreted (RANTES or Ccl5) chemokine suggests a role in the control of inflammatory responses in the epididymis. Whereas similar cells have been described in other mammalian species including humans, further investigation is required in order to characterize and define the functions of these cells.

Clear cells

Clear cells are characterized by an apical pole enriched with mitochondria and display a complete and functional endocytic apparatus. For instance, numerous vesicles, endosomes, coated pits, multivesicular bodies and lysosomes have been observed in clear cells by electron microscopy studies. These cells express the vacuolar proton pump ATPase (V-ATPase), whose activity contributes to luminal acidification in order to maintain spermatozoa in a quiescent state prior to ejaculation (Breton et al., 1996). As observed by high resolution technologies such as helium ion microscopy (HIM) the clear cell apical membrane features microvilli as well as relatively short membrane ridges called microplicae. These membrane protrusions contain a high density of proton-pump V-ATPase and elongate in the presence of several intraluminal factors, including bicarbonate, cAMP, and ATP to increase proton secretion efficiency. Under steady-state conditions, the V-ATPase is distributed between subapical vesicles and the apical plasma membrane of clear cells. However, in response to stimuli originating from the luminal environment (high pH, low bicarbonate concentration, angiotensin II, purinergic agonists), the V-ATPase is recruited into the plasma membrane, which elongates to form extended microvilli. Functional studies have shown that the increase in microvilli length is correlated with an increase in proton secretion into the lumen (Breton and Brown, 2013). Furthermore, clear cells are thought to be endocytic cells that remove proteins from the epididymal fluid in addition to cytoplasmic droplets that detach from spermatozoa during epididymal sperm maturation.

Basal cells

Basal cells are pyramidal-shaped cells located at the base of the epithelium that directly interact with neighboring principal and clear cells through gap junctions. It was recently established that these cells are capable of projecting dynamic cytoplasmic extensions called axiopodia in the initial segment of the rodent epididymis. Axio-podia extensions toward the intraluminal compartment and retractions follow an oscillatory pattern and are proposed to participate in a mechanism of epididymal fluid sampling. Although the role of basal cells remains uncertain, previous studies have reported the presence of enzymes such as the Yf subunit of glutathione-S-transferase (GST), CuZn-superoxide dismutase (SOD), and metallothionein that are involved in the protection against reactive oxygen species. In addition, basal cells were reported to display endocrine properties through the secretion of prostaglandins and to present similar features to adult stem cells. This latter study suggested that basal cells might be multipotent stem cells that have the capacity to differentiate in vitro and to potentially regenerate the epididymal epithelium.

Halo cells

Halo cells are found all along the epididymis, but are more abundant in the proximal regions. They represent a mixture of different immune cells such as helper T lymphocytes, cytotoxic T lymphocytes, and macrophages, and their number increases during aging. The existence of these immunocompetent cells is indisputable but their exact characteristics and their immunological functions remain to be clarified.

Mononuclear phagocytes

Mononuclear phagocytes comprise dendritic cells and macrophages that are in close proximity to the epididymal epithelium. These cells were discovered recently and have been characterized all along epididymides from transgenic mouse models by using different immune cell markers. They surround the base of the epithelium and extend long narrow dendrites between epithelial cells toward the lumen of the proximal epididymal regions. Dendritic cells are also retrieved from normal human epididymides, with specific subsets showing a significant increase under inflamed conditions. While basal cells possess dendritic cell-like features, these two populations are distinct in terms of protein marker expression and are proposed to play distinct functions in the epididymis. Their specific roles throughout the epididymis remain to be addressed.

Conclusion

In vertebrates, the epididymis is an elaborate tubule in which distinct epithelial cell types perform specific functions to ensure the production of functionally mature spermatozoa. While initial studies performed by pioneers shed light on the complexity of this

tissue organization and cell functions, new avenues of exploration are continually opened to uncover the complexity by which somatic and germinal cells collaborate to sustain male reproductive abilities. Unraveling the molecular and cellular processes that affect sperm function are essential for the development of new contraceptive strategies and to better understand the origin of male infertility.

Epididymis: Sperm Maturation and Motility

Introduction

The formation of spermatozoa occurs in the testis in a process known as spermatogenesis. However, often overlooked is the fact that in mammals testicular sperm are nonfunctional. It is only during transit through the long highly convoluted tubule known as the epididymis that sperm undergo maturation and acquire progressive motility and the ability to fertilize an oocyte (Cornwall, 2008). Because spermatozoa are transcriptionally silent, maturation is induced by molecules that are released by the surrounding epididymal epithelium. The epididymis exhibits highly regionalized gene expression with different epididymal segments synthesizing and secreting unique subsets of proteins that can bind to the sperm surface and/or modify existing sperm proteins. This highly segment-specific pattern of gene and protein expression results in a luminal environment that is constantly changing along the length of tubule thereby creating unique microenvironments that are essential for sperm maturation. In addition to different proteins in the lumen, changes in lipids, sugars, and ions, also contribute to the unique segment-specific microenvironment. Thus as spermatozoa migrate through the epididymal tubule from the caput/head to the cauda/tail region, they are on a maturational assembly line, ultimately arriving in the cauda epididymis as a functionally mature cell (Fig. 1). In this article, we will discuss the acquisition of sperm motility and fertility during epididymal transit, modifications in spermatozoa that are important for their maturation, and mechanisms for delivery of maturation-associated molecules to spermatozoa. While most of the experimental work described herein was performed in animal models, parallels can be drawn with the human epididymis which similarly plays essential roles in sperm maturation (Sullivan and Miesusset, 2016).

Sperm Motility Maturation

Perpetuation of the species requires that a single spermatozoon binds and fuses with the oocyte during fertilization thereby delivering its genetic material essential for the formation of the embryo. To accomplish this, spermatozoa must exhibit robust progressive motility that propels the cell up the female tract and provides sufficient force for penetration of the zona pellucida that surrounds the oocyte. Indeed, poor sperm motility is often associated with male infertility. While the sperm head contains the nucleus with DNA, the sperm flagellum contains the motile apparatus that is essential for motility (Fig. 2). The sperm flagellum consists of a connecting piece that attaches the flagellum to the sperm head, midpiece containing mitochondria that provides the energy for motility, and the principal piece and endpiece that generate the waveform pattern of motility. The motility motor of the flagellum is the axoneme which runs from the connecting piece to the endpiece. Composed of microtubules in a 9 + 2 configuration, the axoneme creates the flagellar beat via sliding of a microtubule doublet in relation to adjacent microtubules through the action of dynein arms attached to the microtubules. Accessory components in the flagella include the outer dense fibers and fibrous sheath that assist with maintenance of flagellar structure and beat. Sperm motility also requires energy, namely in the form of ATP that is used by the dynein ATPases, and which is generated by oxidative phosphorylation in the mitochondria and glycolysis in the flagellum and head. More recently, AMP was also shown to modulate flagellar wave form (Vadnais et al., 2014).

Upon entering the initial segment region of the epididymis, spermatozoa possess all the necessary machinery for active motility but only exhibit a slight twitching motion. As spermatozoa progress along the tubule, they gradually acquire the capacity for progressive motility. This maturation is reflected by an increase in the percentage of spermatozoa that exhibit movement and qualitative changes in their motility patterns. Immature spermatozoa exhibit a high amplitude, low frequency flagellar beat and often swim in circles while mature epididymal spermatozoa exhibit a low amplitude, high frequency flagellar beat (Fig. 3). This pattern of motility produces the forward linear progression that propels spermatozoa in a straight line as they swim out of the seminal plasma after ejaculation. In the female tract, additional maturational changes in sperm motility occur that are necessary for egg penetration. It is important to note that the maturational changes in sperm motility that are described here were determined

Fig. 1 Epididymal sperm maturation. Sperm migrate out of the testis into the efferent ducts and then enter the initial segment (IS) region of the epididymis. Spermatozoa then move distally into the caput (head), corpus (body), and then cauda (tail) region of the epididymis where they are stored until release into the vas deferens upon ejaculation.

Fig. 2 Schematic diagram of a spermatozoon. The spermatozoon is composed of a head and flagella. The flagella includes a connecting piece, midpiece, principal piece, and endpiece. The axoneme, which runs within the flagella from the connecting piece to the endpiece, is composed of microtubules in a 9+2 configuration (*right diagram*).

Fig. 3 Motility and fertility maturation in the rodent epididymis. As spermatozoa migrate from the caput to the cauda epididymis, there is an increase in the percentage of spermatozoa that fertilize oocytes and exhibit motility. The sperm flagellar pattern transitions from a high amplitude, low frequency pattern characteristic of immature spermatozoa to low amplitude, high frequency typical of mature spermatozoa. Data presented from Orgebin-Crist, M. C. (1967). Sperm maturation in rabbit epididymis. *Nature* **216**, 816–818; Hinton, B. T., Dott, H. M. and Setchell, B. P. (1979). Measurement of the motility of rat spermatozoa collected by micropuncture from the testis and from different regions along the epididymis. *Journal of Reproduction and Fertility* **55**, 167–172.

following dilution of epididymal spermatozoa into a physiological buffer. In situ, despite acquiring the capacity for motility, spermatozoa are stored in the cauda epididymis in a quiescent state. The mechanism by which cauda epididymal spermatozoa are kept immotile varies between species and includes the presence of immobilin, a protein that increases the viscosity of the epididymal fluid preventing sperm movement (Usselman and Cone, 1983) or acidic pH (Acott and Carr, 1984).

To date the precise mechanisms that are important for the initiation and maturation of sperm motility in the epididymis are not known. Early studies showed that motility could be induced in immature caput spermatozoa by increasing intracellular cAMP suggesting the soluble adenylyl cyclase/cyclic adenosine monophosphate/cAMP-dependent protein kinase signaling pathway is

important, possibly via cross-talk with other signaling pathways (Hoskins et al., 1975; Vadnais et al., 2014). Other signaling pathways important for sperm motility acquisition include phosphoprotein phosphatase I (PPP1) which plays a key role in suppressing sperm motility (Freitas et al., 2017). PPP1 activity is high in caput epididymal spermatozoa which are immotile while PPP1 is inactive in cauda spermatozoa which are motile. PPP1 activity is mediated by its interactions with PPP1R2, a PPP1 inhibitor, that when phosphorylated by glycogen synthase kinase 3 (GSK3) is unable to bind PPP1, making it active. The Wnt signaling pathway is also important for sperm motility maturation since it can mediate GSK3 activity through its binding and activation of low density lipoprotein receptor-related protein receptor (LRP6) which in turn induces GSK3 inhibition (Koch et al., 2015).

Other processes that are important for motility maturation include sperm disulfide bond formation. Immature caput epididymal spermatozoa are sulfhydryl-rich. However, during epididymal transit many sperm proteins are oxidized including those associated with chromatin and tail structures so that mature cauda spermatozoa are disulfide-rich and possess fewer free sulfhydryls (Calvin and Bedford, 1971). Disulfide bond formation stabilizes sperm structures which is an essential part of the maturation process. Indeed, immature caput epididymal spermatozoa induced to become motile by the addition of cAMP phosphodiesterase inhibitors exhibit flagellar angulation with the sperm head bent back on to its flagella (Cornwall et al., 1986). Addition of diamide, a sulfhydryl oxidant, prevented the flagellar angulation suggesting disulfide bond formation is important for maintaining flagellar straightness during motility acquisition (Cornwall et al., 1988). Subsequent studies suggested that adenylyl cyclase plays a role in regulating flagellar stabilization possibly by sulfhydryl oxidation of several sperm protein sulfhydryls including that of fatty acid binding protein 9 (Ijiri et al., 2014).

Acquisition of Fertilizing Ability

During epididymal transit, spermatozoa also gradually acquire the ability to fertilize oocytes in vitro and in vivo. Fertilization competence requires multiple biochemical and physiological changes that occur in spermatozoa and include acquiring the ability to undergo protein tyrosine phosphorylation, bind to the zona pellucida that surrounds the oocyte, undergo the acrosome reaction, fuse with the oocyte plasma membrane, and fertilize the oocyte (Gervasi and Visconti, 2017). Ultimately by acquiring these properties in the epididymis, spermatozoa are then fully capable of undergoing capacitation in the female tract, a last maturational event that is required prior to fertilization. The acquisition of sperm fertility in the epididymis appears to be independent from motility and involves different mechanisms since the site where these two events occur in the epididymis are distinct (Fig. 3). In all species examined, spermatozoa must migrate through the caput region to acquire an ability to fertilize. However, the region where the first fertilizing spermatozoa appear varies with rodent and human spermatozoa acquiring fertility in the proximal cauda epididymis. The acquisition of fertilizing ability also does not correspond with the production of viable offspring. Early studies by Orgebin-Crist (1967) showed that while spermatozoa from the rabbit corpus epididymis will fertilize oocytes, they do not result in viable offspring. In contrast, when ejaculated rabbit spermatozoa were used, fertilization and development proceeds normally and viable embryos are generated. Further studies indicated the loss of embryos that occurred with corpus epididymal spermatozoa was due to a delay in the fertilization process (Orgébin-Crist, 1968). Thus additional maturational changes distal to the corpus region are necessary for normal embryogenesis. To date the mechanisms of how spermatozoa acquire their fertilizing ability remains unclear. However, an infertile phenotype is associated with the loss or modification of many proteins that are acquired by spermatozoa during epididymal transit emphasizing not only a role for these proteins in fertilization but also the complexity of this process (Skerget et al., 2015).

Maturation-Associated Changes in Spermatozoa

As spermatozoa migrate through the epididymis they undergo many modifications including changes in protein, sugar, and lipid content that ultimately contribute to their maturation. Proteomic analyses of spermatozoa isolated from different epididymal regions from several species reveal a highly active remodeling of proteins including those associated with the sperm membrane and acrosome (Belleannee et al., 2011; Labas et al., 2015; Guyonnet et al., 2012). Studies in the mouse epididymis showed that over 700 proteins were added while over 1000 proteins were removed as spermatozoa migrated from the caput to the cauda epididymis (Skerget et al., 2015). Of these, gene ontology (GO) analyses showed that proteins added to spermatozoa during transit were enriched in several categories related to sperm function including those involved in sperm capacitation, sperm-egg recognition, motility, as well as those related to mitochondrial protein processes and high density lipoprotein particle clearance. GO analysis of proteins removed during epididymal transit indicated proteins involved in Golgi transport, ion transport and homeostasis, protein localization, and metabolic processes, possibly reflecting those that had performed remodeling functions during maturation but were no longer needed. Proteomic analyses also revealed maturational changes in the sperm acrosomal matrix during epididymal transit. While changes in proteins associated with the acrosomal membrane are expected, several epididymal secretory proteins also became associated with the acrosomal matrix, an insoluble component of the acrosome, as spermatozoa transited the epididymis (Guyonnet et al., 2012). The acrosome is an organelle associated with the sperm head that plays critical roles in fertilization and thus changes in its structure in the epididymis may be an important maturational process necessary for fertilization.

Posttranslational Modifications

In addition to the gain or loss of proteins, during epididymal transit many sperm-associated proteins undergo posttranslational modifications (PTM) which contribute to sperm maturation. PTM involve the modification of amino acids and the attachment of functional groups such as GPI anchors, acetyl, alkyl, phosphate or glycosyl groups, addition of peptides such as SUMO or ubiquitin, and structural changes such as disulfide bond formation or proteolytic cleavage. Phosphorylation and N-linked glycosylation are the most prevalent PTM as reported in the Swiss-Protein Knowledgebase. Because PTM can affect protein structure, changes in protein localization, interactions, activity, and stability can occur and thus PTMs are a powerful way to fine tune protein function.

Phosphorylation is the addition of a phosphate group to serine, threonine, tyrosine, or histidine amino acids. This requires the transfer of a phosphate group from ATP or GTP to the protein by action of specific kinases while dephosphorylation utilizes protein phosphatases. Both kinases and phosphatases are present in epididymal spermatozoa. Further, changes in protein phosphorylation status have been described in spermatozoa during epididymal transit with corresponding changes in protein localization or function suggesting this PTM plays an important role during sperm maturation. Proteomic studies by [Baker et al. \(2012\)](#), showed changes between caput and cauda sperm in phosphorylation status of different proteins. One protein of particular interest is IZUMO1, a protein essential for sperm-oocyte fusion, that changes localization in the sperm head following phosphorylation, allowing it to participate in fusion with the oocyte ([Inoue et al., 2005](#); [Sosnik et al., 2009](#)).

Glycosylation is an enzymatic process that attaches glycans/sugars to proteins, lipids, or other organic molecules. Changes in both N-linked and O-linked glycosylation have been described in epididymal spermatozoa and thus glycosylation is a significant PTM that modifies epididymal sperm surface molecules important for maturation. Indeed, carbohydrates linked to proteins, lipids, and other molecules form a glycocalyx on the sperm surface that is important for fertilization ([Schröter et al., 1999](#)). Sperm plasma membrane glycoproteins that contribute to the glycocalyx are modified during epididymal transit as shown by changes in lectin binding properties ([Srivastava and Olson, 1991](#)). Also, during epididymal transit spermatozoa acquire a net negative charge likely due to the increase in incorporation of negatively charged sialic acid ([Holt, 1980](#)). Proteomic analyses identified several N-linked sialylated glycopeptides in epididymal spermatozoa including ADAM family members, basigin, and testis-expressed protein 1 ([Villaverde et al., 2016](#)). The changes in the sialic content of these proteins in spermatozoa from different epididymal regions suggest a role in maturation.

Other PTM that occur in spermatozoa during epididymal transit include ubiquitination and protein processing. Ubiquitination is the modification of proteins by the covalent attachment of ubiquitin to lysine residues. Ubiquitination usually earmarks a protein for degradation by the proteasome pathway and indeed defective spermatozoa in the epididymis become ubiquitinated suggesting a mechanism for quality control ([Sutovsky et al., 2001](#)). Other studies suggest the ubiquitin–proteasome pathway may also play a role in fertilization ([Sutovsky, 2011](#)). Many sperm-associated proteins undergo protein processing during epididymal transit. This involves the breaking of peptide bonds between amino acids by specific peptidases and proteases. This can result in changes in protein localization which is thought to contribute to the formation of specific sperm domains ([Phelps et al., 1990](#)).

Lipid Modifications

Maturation in the epididymis is also associated with changes in the lipid composition of sperm membranes. Generally as spermatozoa move from the caput to the cauda region there is a decrease in the cholesterol: phospholipid ratio which correlates with an increase in membrane fluidity ([Jones, 2002](#)). There also is an increase in the ratio of polyunsaturated to saturated fatty acids which may also contribute to membrane fluidity changes. It is likely that increased membrane fluidity in cauda spermatozoa is required for fertilization events including ability to acrosome react and egg fusion.

Migration of Cytoplasmic Droplet

The cytoplasmic droplet is a remnant of germ cell cytoplasm that remains associated with spermatozoa following their release from the testis. During epididymal transit the cytoplasmic droplet migrates from the neck toward the midpiece by mechanisms not understood. In some species the cytoplasmic droplet is discarded by mature spermatozoa and it remains unclear whether retaining the cytoplasmic droplet is associated with infertility. It also is unknown if the cytoplasmic droplet plays a role in sperm maturation although roles in osmoregulation have been proposed ([Fetic et al., 2006](#)). The presence of several enzymes including lysosomal hydrolases and metabolic enzymes including those involved in ATP production in cytoplasmic droplets also suggests a role in the production of energy as part of the maturation process ([Yuan et al., 2013](#)).

Delivery of Maturation-Associated Molecules to Spermatozoa

During epididymal transit, spermatozoa acquire maturation-associated molecules by several different mechanisms. One such mechanism is by extracellular vesicles, including microvesicles and exosomes, which are released from the epididymal epithelium and carry noncoding RNA, lipids, and protein cargo to spermatozoa and function as a means of intracellular communication. Specifically, exosomes in the epididymis, known as epididymosomes, are small (40–100 nm) membrane bound vesicles that transport proteins with proposed functions in fertilization and sperm motility as well as in sperm remodeling to specific sperm domains

and therefore are thought to play important roles in sperm maturation (Rejraji et al., 2006; Sullivan, 2015). Proteomic analyses of isolated exosomes also revealed a number of proteins associated with the ubiquitin–proteasome pathway suggesting additional roles for exosomes in targeting sperm for degradation (Girouard et al., 2011). In support of this, distinct populations of epididymosomes were shown to preferentially bind to defective, dying sperm while other populations bound to viable spermatozoa (Frenette et al., 2010). Thus the diversity of extracellular vesicles in the epididymal lumen likely reflects the many roles they play in epididymal function.

Epididymosomes also carry microRNAs (miRNA) that are delivered to spermatozoa during epididymal transit. Moreover, studies in mouse suggest this process is highly selective as a distinct subset of miRNAs was found only in epididymosomes and spermatozoa and not in the surrounding epididymal epithelium (Reilly et al., 2016; Belleannée et al., 2013). While exosome cargo usually reflects that of its originating cell, the unique populations of miRNAs in epididymosomes and their transfer to spermatozoa led to the suggestion they may function at the time of fertilization where activation of RNA pathways are necessary (Reilly et al., 2016). Epididymosomes also deliver tRNA fragments, which can mediate gene expression, to spermatozoa during epididymal transit. Changes in the levels of tRNA fragments were detected in spermatozoa from mice that had undergone dietary restriction leading to the suggestion that they could affect embryogenesis and play a role in epigenetic inheritance (Sharma et al., 2016).

In addition to delivering cargo to spermatozoa, exosomes released from one epididymal region also have been shown to deliver cargo to downstream epididymal epithelial cells. Indeed, in vitro studies showed that miRNAs and proteins can be transferred from epididymosomes to epididymal epithelial cells in culture (Belleannée et al., 2013). Thus exosomes may be a mechanism by which the luminal fluid can communicate with and regulate epididymal functions. Finally, in addition to classic epididymosomes, the epididymal lumen also contains larger vesicles up to 1000–2000 nm suggesting unique structures/functions that have not yet been determined.

A second mechanism by which maturation associated proteins and perhaps other molecules are delivered to spermatozoa is by the interaction of membrane-less, dense bodies with the sperm surface. Studies by Asquith et al. (2005) showed that dense bodies containing chaperones hsp1 and gp96 were present in the epididymal lumen and that these proteins were later detected on cauda spermatozoa. It was proposed that dense bodies may be a means to deliver chaperones important for the remodeling of the sperm surface during fertilization.

In addition to interactions of extracellular vesicles and dense bodies with spermatozoa, some epididymal proteins are secreted into the lumen by their release from secretory granules in the classic secretory pathway. These soluble epididymal proteins then bind to the sperm surface. Finally, more recently high resolution helium ion microscopy showed direct interactions between spermatozoa in the lumen and the surrounding epididymal epithelial cells raising the possibility for a direct transfer of proteins by these interactions (Păunescu et al., 2014).

Summary

Taken together the maturation of spermatozoa in the epididymis is a complex yet poorly understood process. The transfer of molecules from the epididymal epithelium to spermatozoa is essential for maturation and is mediated by several different mechanisms including epididymosomes that can specifically target delivery to discrete sperm domains, dense bodies, and absorption of soluble proteins to the sperm surface. The delivery of maturation-associated molecules induces changes in sperm structure including the sperm surface via the addition, removal, or modification of existing proteins, lipids, and sugars, ultimately resulting in sperm acquiring motility and fertility.

Gene Regulation in the Epididymis

Overview of Epididymal Function

The epididymis is a single convoluted tubule, through which sperm travel upon release from the testis. The function of the epididymis is to provide the microenvironment and molecular machinery required for the maturation of sperm. Sperm leave the testis morphologically mature, or nearly so, but are unable to swim progressively, or to penetrate and fertilize an oocyte. Both of these functional capacities are acquired in the epididymis in a process referred to as posttesticular sperm maturation. As sperm are largely, if not totally, transcriptionally and translationally inert, the maturation process must be completed using cellular processes that are present in the sperm upon leaving the testis, along with extracellular processes functioning in the luminal fluid of the epididymis. Since the contribution of the epididymal luminal microenvironment is required for sperm maturation, and due to the fact that the maturation process proceeds as the sperm transit the epididymis, the precise regulation of gene expression along the length of the epididymal tubule is critical to the sperm maturation process. Of particular importance is the regulation of genes encoding secreted proteins, as these may interact directly with sperm to facilitate maturation. The maturation produced by secreted proteins occurs either by modifying the sperm in some way (i.e., glycosidases, proteases, etc.), by becoming a component of the sperm surface, or, in some cases, becoming an intracellular sperm protein. In addition, many epididymal proteins are required for maintaining appropriate luminal conditions, such as pH and isotonicity, for sperm maturation and storage. Regulation of genes encoding these proteins is also very important to the maturation process. For a comprehensive review of epididymal development, structure, and function see [Robaire et al. \(2006\)](#).

Anatomy of the Epididymis

The epididymis has gross anatomical regions designated as the initial segment and caput (both in the proximal region), corpus (middle region), and cauda (distal region) [Fig. 1](#). The initial segment is present as an anatomically distinct region in mice and rats. The initial segment together with the caput region comprise the region of the epididymis most active in sperm maturation. The cauda region of the epididymis is where sperm are stored prior to ejaculation. Gene expression in the epididymis was shown many years ago to be carefully regulated in a region-specific manner ([Cornwall and Hann, 1995](#)). There are many genes expressed in the caput epididymis that are differentially regulated in the corpus and/or cauda epididymis. This makes

Fig. 1 Schematic representation of the mouse epididymis showing the caput (*proximal*), corpus (*middle*), and cauda (*distal*) anatomical regions, as well as the segmental pattern comprising each region. Each segment of the epididymis is separated from adjacent segments by a connective tissue septum, creating a unique interstitial environment in each segment. Segment 1 of the mouse epididymis is also denoted as the initial segment. This region is not anatomically distinct in the human epididymis. Drawing by Madeleine Roberts, based on descriptions in Turner, T. T., Johnston, D. S., Jelinsky, S. A., Tomsig, J. L. and Finger, J. N. (2007). Segment boundaries of the adult rat epididymis limit interstitial signaling by potential paracrine factors and segments lose differential gene expression after efferent duct ligation. *Asian Journal of Andrology* **9**, 565–573.

intuitive sense, given the differential function of each region. Upon closer examination, the epididymis is actually subdivided into a series of compartments, the number of which are species-specific, which are each divided by septa that isolate each segment; this creates a series of distinct microenvironments that have been shown to have specific patterns of gene expression (Fig. 1). Expression of many genes along the epididymis, in each of its segments, is effected by androgens and by factors in the luminal fluid that are products of the testis. These two sources of gene regulation are also interdependent for some genes. Specific examples of genes regulated in a segment-specific manner, and by androgens or luminal factors, are detailed below with discussion of what is known of the molecular mechanisms that control their expression.

Regional Gene Expression

Early studies on epididymal gene expression and protein production characterized the predominant secretory proteins of the epididymis. The major secretory products were first identified by gel electrophoresis and given letter designations (Proteins A, B/C, and D/E). This work was followed by the isolation and characterization of several proteins abundant in epididymal fluid (Cornwall and Hann, 1995). Some of these proteins were shown to be enriched in, or specific to, the epididymis. Most of these proteins were shown to have a regional pattern of expression along the epididymis. For instance, cystatin-related epididymal spermatogenic protein (CRES), protein B/C, and glutathione peroxidase 5 (GPX5) are reproductive proteins with expression in the caput epididymis, while sperm associated antigen 11 (Spag 11 or HE2) is expressed in the corpus, and WAP four-disulfide core domain 2 (Wfdc2 or HE4) and cysteine rich secretory protein 1 (Crisp1) are expressed primarily in the corpus and cauda. Even genes with well-characterized expression in other tissues, such as proenkephalin, CRBP, and HGF, have region-specific expression in the epididymis. This early molecular work supported the general hypothesis that regional gene expression patterns along the length of the epididymis are key to the function of the epididymis.

With the advent of microarray technology, it became possible to assay the majority of mRNA transcripts along the length of the epididymis, and to determine the overall patterns of regional gene expression. Using this technology, the mouse epididymis has been shown to express over 2500 genes in the caput, corpus, and cauda epididymis (Chauvin and Griswold, 2004). Of these, there was enriched expression of 162 genes in the caput, 55 genes in the corpus, and 133 genes in the cauda, providing further evidence for extensive region-specific gene expression in the epididymis.

Gross dissection of the epididymis into initial segment, caput, corpus, and cauda regions is sufficient to demonstrate region-specific gene expression. However, as noted above (Fig. 1), each of these regions can be further subdivided into segments of coiled epididymal tubule separated by distinct septal boundaries (Turner et al., 2007). The number of these boundaries is maintained by a connective tissue septum. Each of these segments is thought to create a unique microenvironment that supports segment-specific function, including gene expression. A powerful demonstration of the segment-specific function of the epididymis was provided by experiments that isolated segment 1 or segment 2 of the rat epididymis, followed by injection with growth factors epidermal growth factor (EGF), fibroblast growth factor 2 (FGF2), or vascular endothelial growth factor A (VEGFA) to stimulate phosphorylation of MAP kinase (MAPK) (Turner et al., 2007). These experiments showed that phosphorylation of MAPK was confined to the injected segment. Concomitant injection of collagenase, to break down the intersegmental septum, with the growth factors, resulted in stimulation of MAPK in the adjacent segment. Thus, it appears that the intersegmental septa provide a functional compartmentalization of the epididymis which contributes to region-specific gene regulation.

Microarray gene expression analysis of the individual segments of the epididymis confirms the hypothesis that these segments are individually regulated, and has allowed for detection of regulated genes that are not detectable when large numbers of segments are combined for analysis (Johnston et al., 2005, 2007). Johnston et al. have used this approach to study epididymal gene expression and have shown that 16,000–17,000 genes are expressed in the mouse and rat epididymis (Johnston et al., 2005, 2007). Of these, 77 and 110 transcripts were found to be epididymis-specific in the mouse and rat, respectively. Among these transcripts were several genes that are known to be specific to the epididymis, including lipocalin 5, glutathione peroxidase, and Adam 7. Using data from the mouse epididymis, over 6000 genes exhibited segment-specific regulation (at least twofold difference between two segments), and over 60 genes were differentially expressed by 100-fold or greater (Johnston et al., 2005). Examples of tightly regulated genes include a disintegrin and metalloproteinase domain (Adam 28), expressed only in segments 1–2, myomesin 2 (*Myom2*), expressed only in segments 6–7, and small muscle protein, X-linked (*Smpx*), expressed only in segments 8–10. There are also families of genes, such as the defensins, aquaporins, and lipocalins that are regionally expressed, with various members of the families expressed in different regions of the epididymis (Belleannee et al., 2012b).

Although the segment-specific control of gene expression is now well established in the epididymis, the mechanisms responsible for this regulation are not well understood. It seems likely that paracrine regulators in each segment play a role, as well as regulatory molecules found in the lumen of the epididymal fluid.

Regulation of Epididymal Gene Expression by Androgens and other Testicular Factors

Much of the male reproductive tract, including the epididymis, requires androgens for normal growth, development, and function. Testosterone, produced by the testicular Leydig cells, reaches the epididymis by two routes: peripheral circulation

and by transport in the luminal fluid. Testosterone transported in the luminal fluid is predominantly bound to androgen binding protein (ABP) and taken up in a receptor-mediated fashion by the epididymal epithelium. Testosterone is a sex steroid hormone that can be converted to estradiol by aromatization or reduced to 5-hydroxy-testosterone (DHT) by 5 α -reductase. DHT has an affinity for the androgen receptor that is approximately 10 times that of testosterone. Local conversion of testosterone to estradiol is of major regulatory importance in the efferent ducts, which are the excurrent tubules leading to the epididymis. DHT, on the other hand, is the predominant sex steroid required for normal function of the epididymis, supporting differential gene expression along the length of the epididymis (Robaire and Hamzeh, 2011). Early studies showed that androgen withdrawal, typically achieved by castration, results in profound changes in the epididymis including alterations in protein secretion and gene expression, and pronounced changes in cellular morphology in the epididymal epithelium (Robaire and Henderson, 2006; Robaire et al., 2007).

A simple model for androgen withdrawal is bilateral castration, effectively removing the source of androgens from the animal. Androgen can then be replaced by injections, or chronically using testosterone-filled silastic implants, to demonstrate the restoration of androgen-dependent functions of the epididymis. However, castration also removes all other contributions of the testis to epididymal fluid, including sperm. Therefore, this may also remove other potential regulatory factors that may be required for normal epididymal function, including some functions that are also dependent on androgen. To isolate the effects of luminal components from androgens on epididymal gene expression, the efferent ducts can be ligated, thus eliminating testicular luminal factors while keeping androgen levels normal. Likewise, unilateral castration leaves the ipsilateral epididymis free of testicular factors while still influenced by normal circulating testosterone levels. The combination of these approaches allows the separation of the effects of testicular factors in the luminal fluid from the effects of androgens. Using these techniques in combination, Garrett et al. showed that while proenkephalin, Protein B/C, and Protein D/E (Crisp1) are all decreased by castration, only Protein B/C and Protein D/E are restored with exogenous testosterone treatment. Proenkephalin requires testicular factors for normal levels of expression. Similar regulatory requirements have been shown for several other proteins as well (Hinton et al., 1998).

Comprehensive gene expression studies have demonstrated that the caput epididymis has several hundred genes that are regulated by androgens, with roughly half of them upregulated and half downregulated (Chauvin and Griswold, 2004; Robaire and Hamzeh, 2011). The effect of androgen withdrawal is progressive over several days, with over 1000 genes affected. The restoration of gene expression by exogenous androgen starts within hours of administration of androgen and continues over several days. However, gene regulation is not returned completely to normal by androgen administration, emphasizing the importance of luminal factors in the regulation of epididymal gene expression.

The families of genes controlled by androgen in the epididymis, as determined by transcriptional profiling experiments, included many different required cellular pathways such as metabolism, transport, proteolysis, and immune response, as well as cell signaling, signal transduction, and transcriptional regulation (Chauvin and Griswold, 2004; Robaire et al., 2007). Many of the transcripts induced by androgen replacement form parts of intact pathways that may shed light on the central action of androgen in the epididymal epithelium. Among the proteins increased by androgen is insulin-like growth factor 1 (IGF1), which is functionally linked to several other proteins that are also induced after 1 day of androgen treatment of castrated rats (Fig. 2) (Robaire and Hamzeh, 2011). These gene expression clusters, with IGF1 and EGF centrally located, suggest that these growth factors may be central to the normal gene expression profiles of the epididymis that are supported by DHT.

Mechanism of Androgen Gene Regulation

Dihydrotestosterone is the active form of androgen acting in the epididymis (Robaire and Henderson, 2006). The converting enzyme 5 α -reductase (5 α R) is found along the entire length of the epididymis and effectively converts testosterone to DHT in the epididymal epithelium. Many of the effects of androgen withdrawal by castration are mimicked by the administration of 5 α -reductase inhibitors, and sperm from rats treated with such inhibitors have decreased motility and abnormal morphology. There are two transcripts that encode 5 α -reductase in the epididymis. 5 α -reductase type 1 is expressed most highly in the initial segment, whereas the type 2 transcript is expressed throughout the length of the epididymis and most highly in the caput. Ligation of the efferent ducts results in a significant decrease in the expression of 5 α R in the epididymis, with the most pronounced effect in the proximal part. This requirement for luminal factors for the proper support of gene expression has been indicated for a number of other proteins in addition to 5 α R, including proenkephalin, CRES, and gamma-glutamyltransferase (GGT) (Hinton et al., 1998). Although the expression of 5 α R is dependent on luminal factors, the identity of these factors has not been determined. It has been proposed that ABP could be the luminal factor responsible, as it is taken up in a receptor-mediated fashion by the epididymal epithelium. Fibroblast growth factor 2 (FGF2) has also been proposed as a luminal regulator of epididymal gene expression. Regardless of the identity of the luminal factor(s) responsible, it seems clear that both luminal factors are required for normal androgen regulation of the epididymal epithelium.

The classic pathway for androgen regulation of gene expression involves binding of testosterone or DHT to the androgen receptor (AR), followed by translocation of the AR to the nucleus where it binds to androgen response elements (ARE) in the regulatory region of androgen-responsive genes. Additional levels of regulation are provided by co-activator proteins that bind to the AR and modulate its activity. These co-activators are often responsible for the differential expression of androgen-regulated genes in different tissues and cell types, and under varying physiological conditions. Such co-activators may explain, at least in part, the

Fig. 2 A map of genes that respond within 24 h to administration of dihydrotestosterone in the androgen-deprived epididymis in vivo. This image shows only the genes that have been documented in the literature to have a primary interaction with one another. These interactions include effects on gene expression, regulation, protein modification and/or protein–protein binding. Note the central effect of DHT on gene networks involving IGF1 and EGF. Drawing based on information in Robaire, B. and Hamzeh, M. (2011). Androgen action in the epididymis. *Journal of Andrology* **32**, 592–599.

varying response to androgen by the same genes in an epididymal segment-specific fashion. To date, over 160 different co-activators of the androgen receptor have been described. The mechanism of androgen action via the androgen receptor mediated pathway is summarized in Fig. 3 and reviewed in (Robaire and Hamzeh, 2011).

In addition to the AR-mediated mechanism of androgen action, there appear to be additional pathways for androgen action in the epididymal epithelium that may contribute to androgen-regulated gene expression in the epididymis. Hamzeh and Robaire (2011) demonstrated, using an immortalized epididymal cell line (PC-1), that DHT stimulates a pathway involving the activation of steroid receptor coactivator (SRC) kinase (Hamzeh and Robaire, 2011). Within 1 min of exposure to DHT, phosphorylation of Mitogen-activated protein kinase 3 (MAP3K/ERK1) in PC-1 cells was significantly increased. This increase was blocked by hydroxy-flutamide, a selective antagonist against the androgen receptor. The phosphorylation of ERK was dependent on the activation of SRC, and was downstream of the activation of the IGF1 and EGF receptors. The phosphorylation of ERK results in the activation of CREB which is then responsible for the subsequent modification of gene expression (Fig. 3).

Mechanism of Epididymal Gene Regulation by MicroRNAs

Gene regulation in the epididymis is also under the control of the microRNA (miRNA) regulatory system. Deletion of the Dicer1 nuclease, a key enzyme for the processing of miRNA, in the caput epididymis results in the dedifferentiation of the epididymal epithelium, defects in lipid homeostasis, and an imbalance in sex steroid receptor expression (Bjorkgren and Sipila, 2015). This deletion results in mice that produce sperm with altered lipid composition and are infertile. Decreases in the expression of several epididymal genes, including lipocalin 8, cystatin 8, glutathione peroxidase 5, the estrogen receptors, and the androgen receptor, results from loss of Dicer1 (Bjorkgren et al., 2012). It is not known whether the effects of the Dicer1 knockout is direct on these genes, or secondary to the decreased levels of androgen receptor. However, microarray and deep sequencing experiments have identified expression of miRNAs that pair with potential mRNA targets expressed in the same regions of the epididymis. For instance, miRNAs predicted to target the cystic fibrosis transmembrane conductance regulator (*Cftr*), claudin-10, and GLI pathogenesis-related 1 like 1 (*Glpr1L1*) have been identified and found to be negatively correlated to their proposed target mRNA (Belleannet et al., 2012a). These observations suggest a direct posttranslational regulatory effect on mRNA levels in the epididymis.

MicroRNAs have also been proposed as mediators of segment-specific gene regulation in the epididymis. It is known that certain microRNAs are released from cells (extracellular miRNAs) and participate in cell-to-cell communication. Approximately 300

Fig. 3 Diagrammatic representation of the classic nuclear pathway for androgen-regulated gene expression in a target cell (lower half of figure) and nongenomic signal transduction by androgen via stimulation of the c-steroid receptor coactivator (SRC) tyrosine kinase (upper half of figure). Testosterone enters the cell by passive diffusion where it is converted to DHT, a more powerful androgen, by $5\alpha R$. DHT binds to the androgen receptor and the complex, including one or more co-regulators, is translocated to the nucleus where it interacts with the regulatory region of target genes to either stimulate or suppress their transcription. The androgen receptor—SRC complex signals through the epidermal growth factor receptor (EGFR) and the insulin-like growth factor-1 receptor (IGF1R) to stimulate the rat sarcoma viral oncogene (RAS), resulting in phosphorylation of mitogen activated protein kinase kinase 1/2 (MEK1/2), originally known as extracellular regulated MAP kinase (ERK), either directly or through activation of phosphatidylinositol 3 kinase (PI3K), resulting in activation of cAMP response element binding protein (CREB) which regulates transcription of target genes. Drawing based on information in Hamzeh, M. and Robaire, B. (2011). Androgens activate mitogen-activated protein kinase via epidermal growth factor receptor/insulin-like growth factor 1 receptor in the mouse PC-1 cell line. *The Journal of Endocrinology* **209**, 55–64.

microRNAs have been identified in the caput, corpus, and cauda regions of both human and mouse epididymis and a subset of these (5–28) are region-specific (Belleannee et al., 2012a; Nixon et al., 2015). These results are consistent with a region-specific gene regulatory activity for these microRNAs. In the epididymis, miRNAs are known to be packaged and secreted in epididymosomes, which are small membrane-bound vesicles of epithelial origin. Epididymosomes interact with spermatozoa, transferring both proteins and lipids to sperm (Belleannee, 2015). This same transfer could occur between epididymosomes and epithelial cells at some distance from the site of miRNA secretion. The population of miRNAs found in epididymosomes are distinct from the population isolated from epididymal epithelial cells in the same region of the epididymis, suggesting that a distinct population of miRNAs is secreted for the purpose of regulating genes in cells downstream in neighboring segments (Belleannee, 2015). Taken together, these observations suggest that miRNAs are a possible regulator of segment-specific gene regulation in the epididymis. The potential roles of miRNAs packaged into epididymosomes is summarized in Fig. 4.

Gene regulation by the androgen receptor, and regulation of the androgen receptor itself, is mediated through the direct AR regulation of microRNA29a (Ma et al., 2013). The levels of miR-29a are increased in the epididymis after castration and suppressed by subsequent administration of androgen, suggesting a role of this microRNA in androgen action. The control of miR-29a expression is direct, with the androgen receptor binding directly to an ARE in the miR-29a gene, suppressing its expression. When miR-29a is over-expressed, the resulting phenotype resembles androgen deprivation, with the epididymis being substantially reduced in size, and the expression of the androgen receptor diminished. The AR gene is not, however, a direct target of miR-29a. The suppressive effect of miR-29a on AR expression is mediated by the suppression of IGF1 expression by miR-29a, and also demonstrates that the expression of the AR is increased by IGF1.

Fig. 4 Schematic representation of a segment of epididymal tubule showing apocrine secretion of extracellular vesicles (epididymosomes), packaged with microRNAs, interacting with sperm or with downstream epithelial cells. These extracellular vesicles have a population of microRNAs distinct from those found in adjacent epithelial cells. Some of the extracellular vesicles continue in the luminal fluid and contribute to the composition of the seminal plasma. Drawing by Madeleine Roberts, based on descriptions in Belleannee, C. (2015). Extracellular microRNAs from the epididymis as potential mediators of cell-to-cell communication. *Asian Journal of Andrology* **17**, 730–736.

Other Gene Regulatory Mechanisms

It is well known that the testis requires a temperature $\sim 2\text{--}3^\circ\text{C}$ lower than abdominal temperature for normal sperm production. The epididymis also requires this lower temperature for normal maintenance of sperm storage in the cauda epididymis. Surgical relocation of the epididymis to the abdomen, an experimental model for cryptepididymis that raises the temperature of the epididymis to that of the abdomen, results in altered expression of genes, including *Bcl2* and *bax*, which may be responsible for inducing apoptosis in the cauda epididymis (Jara et al., 2002).

In addition to temperature, normal fluid flow in the epididymis is also required for normal function. Gene expression microarray analyses have shown that vasectomies result in altered expression of several genes in the human epididymis (Thimon et al., 2008). Genes affected include *Crisp1* (the predominant protein secreted in the cauda epididymis), Beta-Defensin 126 (*Defb126*), Disintegrin and metalloproteinase domain-containing protein 7 (*ADAM7*), and epididymal sperm binding protein 1 (*ELSPBP1*). The cause of these gene expression alterations has not been determined but is most likely due to either increases in luminal fluid pressure or altered rates of luminal fluid flow.

Summary

The sole function of the epididymis is to provide the microenvironment necessary for the maturation of testicular sperm to sperm that are fully functional upon ejaculation. The epididymis has no known role in systemic physiology, and is only rarely the site of any disease process. Defects in epididymal function are likely to account for a significant percentage of idiopathic male infertility, especially in those cases where no testicular defect in sperm production can be found. The importance of epididymal function to normal fertility, combined with its specific role in reproduction, make it an attractive tissue to target for the development of male contraceptives. Precise control of gene expression is critical to the normal function of the epididymis and there are many different signaling pathways and cellular processes that control this gene expression. The many facets of carefully regulated gene expression discussed above suggest that there are promising diagnostics for male infertility, as well as points for contraceptive intervention, yet to be discovered in future studies of this critical reproductive tissue.

Vas Deferens

Ryan Flannigan and Marc Goldstein, Center for Male Reproduction and Microsurgery, New York, NY, United States

© 2018 Elsevier Inc. All rights reserved.

Introduction

Development

The vas deferens (VD) is derived from the mesonephric or Wolffian ducts. Here, it is formed from the channel or linkage which forms between the mesonephros to the urogenital sinus. This occurs alongside the ureteric development. The VD then progressively lengthens as it descends along with the testis through the inguinal canal into the scrotum (Gier and Marion, 1970; Hannema and Hughes, 2007).

Function

The VD's primary function is to transport sperm during emission from the epididymis to the ejaculatory duct. This is performed through a rhythmic propulsion of fluid and sperm at the time of emission. The VD also functions to store sperm in conjunction with the epididymis and convoluted VD. The VD produces fluid that facilitates sperm transport, and resorbs dead sperm and sperm parts that aren't ejaculated.

Anatomy and Structure

Anatomy

The VD is between 30 and 35 cm in length, Fig. 1. The proximal 2–3 cm is convoluted in shape as it leaves the epididymis. It travels within the spermatic cord from the scrotum through the external and internal inguinal rings. It enters the pelvis lateral to the epigastric vessels, then courses anterior to the external iliac artery, medially along the pelvic sidewall before it crosses anterior to the ureter as it approaches the bladder and accompanies the seminal vesicle entering the ejaculatory duct at the base of the posterior prostate. The VD is categorized into 5 segments: (1) The paraepididymal segment or convoluted VD; (2) scrotal (straight) segment; (3)

Fig. 1 Demonstrating the anatomical path of the vas deferens. It travels within the spermatic cord from the scrotum through the external and internal inguinal rings. It enters the pelvis lateral to the epigastric vessels, then courses anterior to the external iliac artery, medially along the pelvic sidewall before it crosses anterior to the ureter as it approaches the bladder and accompanies the seminal vesicle entering the ejaculatory duct at the base of the posterior prostate.

Inguinal canal segment; (4) Retroperitoneal segment; (5) Ampulla segment (also convoluted). In both the second and third segments, the VD travels within the spermatic cord, posteriorly between the internal and external spermatic fascias.

Vascular and Lymphatic Supply

The VD harbors an outer adventitia that occupies the primary neurovascular structures. The blood supply is derived from the inferior or superior vesical artery, which are branches of the internal iliac artery (AKA hypogastric artery), from which the deferential artery arises. The venous drainage occurs via deferential veins which drain into the pampiniform plexus toward the testicular end, and into the pelvic venous plexus once in the retroperitoneum. The lymphatic drainage extends into the internal and external iliac nodes.

Structure

The VD measures 1–2.7 mm in outer diameter while the lumen measures 0.2–0.7 mm. The outer most layer consists of the adventitia. Next, the muscularis layer, is composed of a helically oriented outer longitudinal layer, a medial thick circular layer and an inner longitudinal layer, **Fig. 2**. Each muscle cell is surrounded by 6–12 additional cells allowing electrical coupling and facilitates transduction of depolarization from cell to cell ([Koslov and Andersson, 2013](#)). The mucosal layer lining the lumen of the VD consists of pseudostratified columnar epithelium, with a transition of cell type from base to lumen of: principal cells, pencil cells, and mitochondria-rich cells. The thickness of the epithelium decreases from the testis end to the seminal vesicle end. The epithelium is configured into microvilli (steriocilia). Lymphocytes are frequently found among the epithelial cells. Basal cells form a discontinuous layer between the epithelium and the lamina propria which provides an interface to the muscular layers ([Dixon et al., 1998](#)).

Innervation

Autonomic innervation controls both motor and secretory function. Sympathetic nerves originate from preganglionic efferent nerves derived from thoracic and lumbar regions (T10–L2), which then pass through the hypogastric nerves, and convalesce in the pelvic ganglia. Here, the pelvic ganglia also consists of parasympathetic nerves which were derived from the splanchnic nerves consisting of sacral roots 2, 3, and 4. These nerves then proceed to innervate pelvic organs such as the VD. The main trunks exist in the perivascular adventitia around the vessels with the predominance of nerve fibers surrounding the arteries and minimal numbers surrounding the veins. These nerves are generally noradrenergic in nature, however, acetylcholinesterase (AChE) positive nerves also exist in this space. Noradrenergic nerves have been identified to be localized primarily to the lamina propria and are more plentiful near the distal, prostate portion of the VD. In humans, the ratio of axonal varicosities to smooth muscle cells is 1:30. These make up the dominant motor component of innervation for the VD. The noradrenergic nerves contain catecholamine-synthesizing enzymes such as tyrosine hydroxylase and dopamine beta hydroxylase in the majority of intramuscular fibers, and nearly 2/3 contain neuropeptide Y, while only small populations contain enkephalin (ENK), galanin (GAL), somatostatin (SOM), or nitric oxide synthase (NOS). These noradrenergic fibers mediate muscular contraction and transport of sperm. Cholinergic nerves however, localize more commonly within the inner muscle layers and are less plentiful. They contain vasoactive intestinal polypeptide (VIP) and NPY in the intramuscular fibers, and NPY, VIP, nitric oxide synthase (NOS) and acetylcholinesterase in the subepithelial fibers. Purine receptors have also been identified within the autonomic nerves of the VD, but of unknown significance. The sensory nerves transmit signals to the dorsal root ganglia ([Koslov and Andersson, 2013](#); [Dixon et al., 1998](#)).

Fig. 2 Illustration of the cross section of the vas deferens. Outer adventitial layer; muscular layer consisting of outer longitudinal fibers, medial circular fibers, and inner longitudinal fibers; epithelial layer surrounding the lumen.

Clinical Considerations

Clinical Assessment of the Vas Deferens

The scrotal portion of the vas deferens is assessed clinically by palpation. It may also be identified by ultrasound as a tubular structure with the absence of Doppler flow. The pelvic portion of the vas deferens, as it enters the ejaculatory ducts, can be assessed by trans-rectal ultrasound (TRUS). However, neither test is able to determine patency. Thus, if obstruction is suspected by history and physical examination, the intraoperative vasography is necessary to confirm obstruction. Conventionally, formal vasography would be performed by creating a small hemi-vasotomy and injecting radio-opaque contrast into the abdominal lumen while taking an X-ray. However, this is typically reserved for cases that are difficult to diagnose the level of obstruction based upon history and physical. Otherwise, scrotal, inguinal and abdominal VD patency is generally assessed by injecting normal saline or lactated ringers toward the abdominal side. If resistance or reflux is met, then obstruction is likely. In this case, a formal vasogram is indicated. Another option, if obstruction in the inguinal portion of the VD from prior hernia repair is suspected, is to feed the tail of a 2-0 monofilament toward the abdominal side of the VD. The point at which the suture stops likely reflects the point of obstruction. This is a practical solution in many cases but does not have the precision of a formal vasogram when there is no prior hernia repair. An additional option for assessment of the abdominal end involves injecting indigo carmen in the lumen of the VD and determining if there is any collection of blue dye in the urine. This is practical for assessing unilateral obstruction, but not if the suspected obstruction is bilateral as the urine will be already blue in the event that the first side was patent. Assessing the testicular end of a VD requires examining the fluid from the vasal lumen or from a barbotaged specimen if the lumen is dry. This fluid is then examined under a bright-field microscope under 400 x magnification in the operating room. The presence of sperm or many sperm heads proves patency of the epididymis.

Congenital Bilateral Absence of the Vas Deferens

Congenital bilateral absence of the vas deferens (CBAVD) is characterized the absence of the corpora and cauda of the epididymis, absence of the vas deferens and absence of the seminal vesicles. The caput, or at least some of the caput, of the epididymis is usually present, with only the caput present in 21%, caput and corpora in 67%, and caput, corpora and cauda of the epididymis in 12% (Liu et al., 2017). This typically occurs bilaterally but can occur unilaterally. It carries a prevalence of 1% among infertile men and 25% among men with primary obstructive azoospermia (Yu et al., 2012). CBAVD is due to a mutation in the cystic fibrosis transmembrane conductance regulator (CFTR) gene. This gene encodes a salt homeostasis anion channel among epithelial cells. In the event of a CFTR gene mutation leading to loss of function of this gene, thickened secretions typically occur in lung and pancreas. These thick secretions are also thought to be present in the forming vas deferens during development, causing obstruction and subsequently resulting in abnormal development. Over 1950 CFTR mutations have been identified, but fortunately only a subset has been identified to cause disease in an autosomal recessive pattern. Severe, class 1, 2, and 3 mutations in both copies of the CFTR gene lead to cystic fibrosis (CF) which carries a prevalence of 0.03% among the general population but is the most frequently encountered lethal genetic diagnosis among Caucasians (Yu et al., 2012). Mild forms of the mutations, class 4 and 5, may be phenotypically normal or present with CBAVD. Among men with CBAVD, 78% carry at least 1 mutation, and 46% carry 2 mutations, termed compound heterozygotes. Most common alleles found to be mutated among Northern Europeans, include: 5T (25%), F508del (17%), and R117H (3%) (Yu et al., 2012).

Clinically, these men present with low volume, clear, watery semen and low semen pH due to atrophic seminal vesicle or obstruction of seminal vesicle ducts or ejaculatory ducts. In these men, the semen is comprised only of clear, acidic prostatic fluid. They are amenable to epididymal sperm extraction from the caput of the epididymal remnant. This may be performed by percutaneous epididymal sperm aspiration (PESA) Fig. 3A, or microsurgical epididymal sperm aspiration (MESA) Fig. 3B. Sperm is successfully retrieved using PESA in 61%–96% of patients, and yields thousands to millions (Esteves et al., 2011). MESA is the gold standard with successful sperm retrieval in 96%–100% of patients, yielding 15–95 million sperm (Bernie et al., 2013) and pregnancy and live delivery rates of up to 70%. IVF/ICSI is typically required in most cases. All patients presenting with CBAVD should receive CFTR testing for both the patient and their partner, and have an informed discussion with the clinician or a geneticist regarding risk of CF to the offspring. Men presenting with vasal agenesis should also receive an abdominal ultrasound to evaluate for renal agenesis, since this is present among 73.3% of men with unilateral absence of the vas deferens and 11.8% among CBAVD (Salwan and Abdelrahman, 2017).

Duplication Anomalies

Duplication of the vas deferens is exceedingly rare. Only 28 case reports have emerged in the literature. These have been found during orchidopexy, varicocelectomy, inguinal hernia repair, vasectomy and radical prostatectomy. It is thought to occur secondary to a transverse division or duplication of the central portion of the mesonephric (Wolffian) duct during organogenesis. These can be classified as: Type 1, multiple vas deferens without polyorchidism; type 2, multiple vas deferens with polyorchidism; type 3, false poly-vas, with ectopic ureter draining into the ejaculatory system (Breitinger et al., 2016).

Ectopic Vas Deferens

Ectopia of the vas deferens is rare. The ectopic VD may connect to the ureter or the bladder. During embryogenesis, the ureter arises from a bud of the Wolffian duct and connects to the urogenital sinus via a channel. This channel is assimilated with the vas deferens

Fig. 3 (A) Percutaneous epididymal sperm aspiration (PESA). This is performed under a local anesthetic, and a 21–26-gauge needle is inserted into the caput of the epididymis and sperm is withdrawn. (B) Microsurgical epididymal sperm aspiration (MESA). This is performed under a general anesthetic. The testis is delivered, and the tunica vaginalis is opened. The caput of the epididymis is gently reflected and the tunical surface is incised exposing the 6–11 efferent ducts. One dilated duct is punctured and sperm is retrieved with a glass micropipette via capillary action.

arising also from the Wolffian duct and both enter the primitive bladder. Normally, the portion of the primitive bladder that the VD inserts into becomes the posterior urethra, namely the verumontanum; however, if failure of the primitive bladder migration occurs, then the VD remains inserted into the bladder. If the primitive bladder fails to obliterate the bridging tissue between the VD and the ureter, then the final position of the VD orifice inserts into the ureter or the ureter inserts into the VD. Ectopic VD may present with UUTI's, vesicovasal, or vesicoureterovasal reflux causing epididymitis, and possible scrotal abscess. Associated conditions include imperforate anus and renal dysplasia (Saifee and Modi, 2016).

Prostate—Overview

Takeshi Sasaki, Omar E Franco, and Simon W Hayward, NorthShore University HealthSystem, Evanston, IL, United States

© 2018 Elsevier Inc. All rights reserved.

General Description

The prostate is a secretory glandular organ located at the base of the urinary bladder, it surrounds the urethra and is found in most mammals. The structure of the prostate varies widely between species, in humans the gland is a compound structure composed of branched ducts lined with secretory epithelial cells surrounded by smooth muscle. In young men the prostate is described as approximately the size of a walnut. The prostate secretes a slightly alkaline fluid that in humans comprises around a third of the ejaculate, most of the balance being made up of seminal vesicle (SV) secretions. The alkaline nature of the prostatic secretions provides protection for sperm from the more acidic vaginal environment, contributing to increased sperm motility and survival, thus positively contributing to fertility. Development and adult function of the prostate is dependent upon androgens produced primarily in the testes, although in humans there is also a small, but significant, adrenal contribution.

Interest in the prostate stems mostly from the three common disease conditions that are associated with it, prostate cancer, benign prostatic hyperplasia (BPH) and prostatitis with associated chronic pelvic pain syndrome. These conditions are major causes of morbidity (suffering) and, in the case of prostate cancer, mortality (death) in the male population.

Development

The early embryo is composed of three tissues; ectoderm, which becomes the skin and skin derivatives such as sweat and mammary glands, endoderm which will form the gastro-intestinal tract and derivative organs such as the liver, and, the mesoderm which exists between the other two layers and gives rise to structures such as connective tissues, muscle and various mesodermally-derived epithelial organs such as the kidney. The prostate is derived from the cloaca representing the caudal (posterior) end of the embryonic gut. This is in contrast to the adjacent seminal vesicles and ureters, which are derived from the primitive Wolffian duct, a mesodermal derivative formed by condensation of mesenchyme into epithelium. Thus the SV and ureteral epithelium are of mesodermal origin while the bladder, prostate and urethra epithelia are all endodermal in origin.

In reptiles and birds the separation of the urogenital and gastro-intestinal tracts is internal with feces, urine, eggs and sperm all exiting (in most species) through the cloaca at the caudal end of the gut. Most birds do not have a penis, mating by touching their cloacae together, although some groups, such as ducks, do have a reproductively functional penis. During the embryonic development of mammals, however, the cloaca is subdivided by the formation of the urorectal septum, into the urogenital sinus (UGS) ventrally (towards the front) and the rectum and anal canal dorsally (behind the bladder and prostate). In humans this process starts around 4 weeks post conception and is completed by 6 weeks, in mice the corresponding period is embryonic days 12–14. As a result of this subdivision of the cloaca, mammals have a complete separation of the gastro-intestinal and genitourinary tracts, with discrete evacuation routes for feces (the anus) and urine (the urethra).

Following the subdivision of the cloaca the upper end of the UGS ultimately forms the urinary bladder in both males and females while the lower portion develops, under the influence of sex steroid hormones, to form the prostate in males and the upper portion of the vagina in females. Staack et al. presented a well described and beautifully illustrated paper showing this process in the mouse (Staack et al., 2003).

Development of the prostate begins with the growth of prostatic buds from the fetal UGS starting at about 10 weeks postconception in the human, or at 19 days of gestation in the rat and at 17 days in the mouse. Androgens produced in the testes act on androgen receptors (AR) in the urogenital sinus mesenchyme (UGM) to induce developmental programs including epithelial budding, proliferation, arborization and canalization giving rise to tubular structures lined with tall columnar secretory epithelium surrounded by smooth muscle that differentiates concurrently with the epithelial developmental program. Prostatic ducts differentiate in a proximal to distal direction (from the urethra to the ductal tip) in the growing prostate starting as a solid cord of epithelial cells the tips proliferate and as the cord grows luminal and basal cells differentiate. The epithelium undergoes ductal canalization at the point at which luminal and basal cells become distinguishable setting up cells that can respond to normal functional signals, notable testicular androgens, and initiate and maintain the expression of characteristic secretory markers such as the kallikrein serine protease, prostate specific antigen (PSA). In adulthood, androgens act upon prostatic smooth muscle (which expresses AR) to maintain a fully differentiated growth-quiescent epithelium, and on the prostatic epithelium to induce and maintain secretory function. These events are mediated by the actions of androgens on the stromal cells, with the role of the epithelial AR apparently being restricted to regulating secretory functions.

In humans and common laboratory animals such as mice, the structure of the prostate is relatively stable throughout the year. However in many seasonally breeding animals, the organ responds to changes in testicular size and androgen production that occurs during the breeding season. This allows the organ to grow and function when needed and then reduce in size through apoptosis (programmed cell death) reflecting the reduced testosterone levels in the rest of the year. This response is mirrored in some ways by the various forms of therapy designed to deprive the prostate of active androgens to induce shrinkage in BPH and proliferation and metastasis in prostate cancer.

Cell Types and Structure

Epithelial cells cover the various internal and external surfaces of the body. They have many forms that relate to specific functions. A familiar example is the keratinized squamous epithelium that forms the skin, providing a tough waterproof layer covering the body surface. There are many specialized epithelia including those of the intestine, where cells that secrete digestive enzymes and adsorb nutrients are found, and secretory cells in the breast and prostate that make and secrete the components of milk and prostatic fluid respectively.

The prostatic ducts empty into the urethra which is lined by a so-called transitional epithelium, a specialized lining that has evolved to separate urine from the rest of the body, incorporating a waterproof layer with the ability to cover surfaces of varying volume. Transitional epithelium covers the whole urinary tract from the renal calyces and pelvis, through the ureters and urinary bladder to the distal end of the urethra. In humans transitional epithelial cells cover the proximal 2 mm or so of the prostatic ducts. There is then an abrupt shift in cellular phenotype to a stratified columnar or stratified cuboidal phenotype with basal epithelial cells and secretory luminal cells.

The basal epithelial cells of the prostate, like those in many other organs are somewhat flattened and lie along the epithelial basement membrane (Fig. 1A and B). They express an array of characteristic markers including p63 and cytokeratins 5 and 14. However, unlike the basal epithelium of organs such as the mammary and salivary glands, prostatic basal cells are not myoepithelial in nature, meaning that these cells have no muscular contractile action. Milk and saliva are moved through the alveolar and ductal structures of the breast and salivary gland by contractions of the myoepithelium. In contrast the prostatic secretions are voided by the overall contraction of the smooth muscle of the prostate during ejaculation. The function of prostatic basal epithelium has been the subject of much debate, with no definitive conclusions. Possible roles include maintaining ductal structure—these cells have long processes that surround the ducts which may be suggestive of a structural role, and while prostatic development is possible, in their absence, at least in experimental models, such structures seem to be subject to extreme responses to hormonal changes (Kurita et al., 2004). Basal epithelial cells may also be involved in the transportation of lipids or nutrients to the luminal epithelium, since lipid droplets are noted in the basal cells and lipids are required for the generation of secretory granules in the luminal cells.

Luminal epithelial cells line the prostatic ducts, depending upon the region of the prostate these are cuboidal to tall columnar in shape, and are active secretory cells manufacturing and secreting the components of the prostatic fluid (Fig. 1A and B). Luminal epithelial cells characteristically express cytokeratins 8 and 18, they also almost uniformly express the androgen receptor, which functions to regulate the expression of a number of the characteristic proteins expressed by the prostate, notably including PSA and prostate-specific acid phosphatase.

The epithelial tissue also contains rare neuroendocrine cells, these are hard to identify visually but can be seen clearly using immunohistochemical staining for chromogranin A or synaptophysin. These cells are sparse throughout the prostate with individual cells seen occasionally in ducts and glands. The exact role of these cells in the prostate is unclear, however they are similar to networks seen in other organs allowing some speculation. The neuroendocrine cells have long branched dendritic processes and seem to communicate with the nonneuroendocrine prostatic epithelium through the use of neuroendocrine secretory granules correlating to a number of known products. The cells appear to be innervated and represent a potential communication network throughout the prostate allowing regulation of growth differentiation and secretory activity of the epithelium through paracrine and neurocrine mechanisms.

Fig. 1 Major cell types found in the prostate. (A) Representative images of hematoxylin and eosin staining of normal human prostate (original magnification $\times 1000$). V, vessel. (B) Stylized diagram depicting major cell types in the prostate. The epithelium is composed of secretory luminal cells, basal cells that line the basement membrane, neuroendocrine cells that are normally rare but can expand in advanced cancer, and intermediate cells associated with proliferation. The stroma surrounding the epithelial cells is a complex mix of smooth muscle, fibroblasts, endothelial cells and immune/inflammatory cells infiltrate along with blood vessels and nerves. Panel B modified from Strand, D. W. et al. (2016) *Differentiation* 91, 141.

The prostatic stroma, the nonglandular components of the organ, is predominantly smooth muscle and fibrous tissue (often described as a fibromuscular stroma) with associated blood vessels and nerves (Fig. 1A and B). The stroma typically makes up approximately half of the total volume of the prostate. Stromal cells play an important role in both the differentiation and development of the prostate as well as the support of normal prostatic architecture and function. The prostate is surrounded by a fibrous capsule that is penetrated by various nerves that can provide a route for the invasion of tumor cells through the capsule in prostate cancer. Extracapsular extension of a tumor is a quantifiable early negative prognostic marker in the progression of prostate cancer. The prostatic stroma also plays an important role in both the negative and positive regulation of prostate cancer growth and is a potential target for therapy in early stage prostate cancer patients.

Prostatic Anatomy

Over several decades a number of different animal species have been used to provide in vivo models of prostate development and disease. The most notable among these have been mice, rats, dogs, and various nonhuman primates. These species have inherent advantages and disadvantages. The principle disadvantage of most animal prostates as models for the human organ is the profound structural differences between the single lobed human organ and the multilobed organ found in most other species and especially obvious in laboratory rodents. This difference is reflected in the types of disease found in human and non-human prostates, with benign prostatic hyperplasia, which is the most common abnormality in the human prostate, being reported only in dogs and chimpanzees. Therefore while mice and rats, for example, are relatively cheap and easy to maintain, results obtained from them are not necessarily directly applicable to the human condition. In mice and rats the prostate is composed of four paired lobes (anterior, dorsal, lateral and ventral prostate) designated by their position around the urethra (Fig. 2). These lobes grow out into the surrounding peritoneal space and are not encapsulated in the manner of the human organ.

Dr. John McNeal, a pathologist working at Stanford University, developed the nomenclature that is now most commonly used to describe the structure of the human prostate (McNeal, 1984). McNeal divided the prostate into histologically distinct and anatomically separate areas. These are; nonglandular fibromuscular stroma surrounding the organ and the peripheral, transitional and central glandular zones containing a complex, yet histologically distinct ductal system (Fig. 2). The central zone is a wedge of glandular tissue making up most of the base of the prostate and surrounding the ejaculatory ducts. The peripheral zone comprises most of the remainder of the gland surrounding most of the central zone and extending to partially surround the distal portion of the urethra. McNeal also identified the transition zone a smaller, glandular region which surrounding the prostatic urethra.

The peripheral zone is the principal site of prostatitis and carcinoma of the prostate. The peripheral zone ducts exit directly laterally from the postero-lateral recesses of the urethral wall. The system consists of small, simple round to oval acinar structures emptying into long narrow ducts surrounded by a stroma of loosely arranged and randomly interwoven muscle bundles. This area is

Fig. 2 Structure of human and mouse prostate. (Left) Diagram depicting the three major prostatic zones of the adult human prostate described by McNeal: central zone, peripheral zone, and transitional zone. (Right) Diagram depicting the four major prostatic lobes of the mouse prostate: lateral prostate, dorsal prostate, ventral prostate, and anterior prostate. Reproduced from Aaron, L., Franco, O.E., and Hayward, S. W. (2016) Review of prostate anatomy and embryology and the etiology of benign prostatic hyperplasia. *The Urologic Clinics of North America* 43, 279–288.

the principle site of prostatitis and carcinoma of the prostate although not of BPH. Within the peripheral zone is included the proximal urethral segment of the prostate. The central zone ducts closely follow the ejaculatory ducts. These ducts and acini are large and of irregular shape in cross section. The acini are polyhedral. The muscular stroma of the central zone is much more compact than in the peripheral zone. The transitional zone immediately surrounds the urethra between the bladder and the verumontanum. This is a small volume of the prostate, perhaps 5% in the normal organ, but is the principal site of BPH pathogenesis. Nodular expansion of this region of the prostate results in compression of the urethra and the partial bladder outlet obstruction associated with BPH.

Various authors have suggested a homology between the lobes of the rodent and zones of the human prostate. However such parallels are, at best, weak, the 2001 Bar Harbor Consensus meeting concluded that “there is no existing supporting evidence for a direct relationship between the specific mouse prostate lobes and the specific zones in the human prostate” (Shappell et al., 2004).

The prostate, like many visceral organs, is surrounded by an adipose depot known as periprostatic fat. This is a potential energy reserve, source of lipids, adipochemokines and inflammatory cells that may be significant in prostate cancer and BPH pathogenesis. At present there is little information available on the relationship between the prostate and this adjacent tissue.

Diseases of the Prostate

The source of much of the interest in such a small organ is its outsized propensity for diseases that cause extensive morbidity and mortality. Prostate cancer, BPH and prostatitis are the three major prostatic disease conditions and will be addressed briefly here.

Prostate Cancer

Prostate cancer is the second most commonly diagnosed non-skin malignancy in American men and the second leading cause of cancer deaths, with approximately 180,000 new cases and 26,000 deaths projected by the American Cancer Society in 2016. That being said, prostate cancer is a disease that far more men will die with, rather than from. Prostate cancer is commonly discovered following a routine blood test for serum PSA. This test has become controversial recently because its widespread use has resulted in the diagnosis of a large number of prostate cancers that would likely not have threatened the life of the patient had they remained undiagnosed. This has resulted in a high level of surgery for prostate cancer, with in excess of 40 prostates excised from patients for every life saved from the disease. Given the level of iatrogenic morbidity (suffering resulting from the intervention) from this surgery this was considered by many to be excessive overtreatment of the condition and as a result the PSA testing guidelines have been redrawn.

Risk factors for prostate cancer include race and family history. Certain inherited genetic mutations, for example in the BRCA1 and 2 genes, are also associated with increased risk of prostate cancer and with more aggressive disease. A patient with a raised PSA level and/or a suspicious digital rectal examination or transrectal ultrasound (TRUS) will normally undergo a prostatic biopsy. This involves the collection of a number of needle cores (typically a dozen or more) using a TRUS-guided approach through the rectum. These cores are then sent for examination by a pathologist who will diagnose cancer or other lesions using established grading scores. In prostate cancer the Gleason grading system (graded 1–5) is most commonly used with the two most common areas in the sample being assessed to give a combined Gleason score from 2 to 10. In general, and in the absence of other factors, areas of Gleason grade 3 or lower (and scores of 3 + 3 or less) are considered to be disease with a lower risk of progression. It should be noted that a positive biopsy always indicates the presence of cancer, but gives little more than an outline of how extensive the tumor might be. It should also be noted that there is a strong possibility of a false negative result as the chance of missing a small tumor even with a TRUS-guided needle biopsy is significant. Thus there may well be a need to re-biopsy a patient with a negative result at a later date.

Patients with high grade localized tumors (contained within the prostatic capsule, or locally invasive) will most likely undergo prostatectomy to remove their entire prostate. Historically this was an “open” operation but is now mostly performed robotically, a less invasive approach with better recovery times. Patients with disease that has characteristics representing a low risk of progression may be offered Active Surveillance (AS) as an alternative approach. Under an AS protocol patients are routinely monitored and surgical intervention may occur should their disease be found to progress, however in the interim, and for many patients this can be a successful long-term approach, this allows them to avoid an unnecessary surgery and possible iatrogenic complications that can include impotence and urinary incontinence.

Prostate cancer, at initial diagnosis, is almost always an adenocarcinoma. By definition, a carcinoma is a tumor derived from epithelial cells, and is a class that includes most common human cancers. An adenocarcinoma has glandular characteristics, often reflecting the organ of origin. Precursor lesions include prostatic intraepithelial neoplasia and prostatic inflammatory atrophy. Cancer arises from an accumulation of genetic alterations occurring in the epithelial cells of the tumor. This results in structural changes affecting the phenotype (defined in terms of cellular and nuclear shape and characteristics) of the epithelium and associated changes in the stromal cells resulting from the loss of normal signaling between epithelial and stromal tissues.

A patient whose disease fails surgical therapy, marked by an increase in serum PSA, a so called biochemical recurrence, or by the detection of metastatic lesions will undergo a series of medical interventions. These will most likely include some form, or possibly multiple forms of androgen ablation therapy aimed at suppressing the production and/or actions of androgens in the prostate. Over the last few years a large armamentarium of new drugs have been developed to tackle late stage hormone resistant prostate cancer. At present none of these is curative, however survival times continue to improve.

Benign Prostatic Hyperplasia (BPH)

BPH is not usually a life threatening condition in countries with well developed healthcare systems. This was not always the case and unrelieved urinary retention caused by BPH can have negative consequences on both the urinary bladder and kidneys, and can ultimately lead to death if not relieved.

BPH is found histologically in the vast majority of aging men. In 2007 there were 1.9 million diagnoses of the condition and 120,000 surgeries were performed to relieve symptoms in men who did not respond to medical interventions. The annual direct cost of the disease is several \$bn, and the incidence is increasing as the population ages.

The pathogenesis and progression of BPH is not well understood. It has long been known that the major risk factors were aging and the presence of functional testes. So BPH has long been considered to be a product of sex steroid action including changes in the ratio of testosterone to estrogen upon an aging prostate. However, this is a complex disease and multiple mechanisms are almost certainly active in many patients. A number of comorbidities that are associated with inflammation, including obesity, metabolic syndrome and type 2 diabetes appear to play an important role in disease progression. There is broad recognition that BPH might result from more than one initial cause. A complicating factor is that patients tend to present with a profile of lower urinary tract symptoms (LUTS) that can result from a number of causes. These symptoms are assessed by the International Prostate Symptom Score (IPSS). A diagnosis of BPH normally includes checking the volume of the prostate using TRUS to confirm that this is the cause of the problem. Three medical approaches to the disease have been developed, these are 5 α -reductase inhibitors (5ARIs), drugs that inhibit the conversion of testosterone to the biologically more active dihydrotestosterone, these drugs cause prostate cell death and reduce the size of the organ over time; α -adrenergic blockers target the dynamic muscular component of LUTS relaxing the smooth muscle and allowing better urine flow; Phosphodiesterase (PDE) inhibitors are a frontline treatment for erectile dysfunction that also show activity affecting smooth muscle tone in the prostate. PDE5 inhibitors can be combined with α -blockers to provide an additive effect. General practice is currently focused around the idea that patients with a large prostate benefit from the addition of a 5ARI to an α -adrenergic blockers as this will both shrink a large prostate over time and relax the prostatic muscle. Although many men have a prolonged response to existing agents, a significant number (20%–25%) have side effects severe enough that they do not remain compliant with the therapy and around a third progress to surgical intervention even in the face of treatment. This represents many surgeries in elderly men, who may not be optimal candidates for such procedure.

A clearer understanding of the specific manner in which specific comorbidities contribute to benign prostate growth would allow for the development of new medical approaches for patient subpopulations. Two classes of drugs for such a large patient population results in very limited personalization of therapy, and new approaches to this condition are certainly needed.

Prostatitis

Prostatitis is a symptomatic inflammation of the prostate. There are a number of forms of prostatitis that reflect the complexity of the condition. Bacterial prostatitis can be either acute or chronic in nature. The causative agents include bacterial organisms similar to those causing urinary tract infections and sexually transmitted diseases, notably *Neisseria gonorrhoeae*. These conditions cause local pain, edema, swelling and possibly fever. Acute bacterial prostatitis can usually be treated with antibiotics and will resolve, while the chronic condition can be more challenging to treat effectively.

The most common prostatitis diagnosis however is, chronic abacterial disease. There is no obvious infectious organism and the symptoms, dysuria and low grade pelvic pain do not respond to antibiotics and has become known as chronic prostatitis/chronic pelvic pain syndrome (CP/CPPS). A role for bacteria in this condition has been largely discounted by the field and symptomatic links to interstitial cystitis suggest that the causes of the condition may relate to chronically activated pelvic nerves. The diagnosis of CP/CPPS is complex and not entirely agreed upon and the treatment can follow many different routes including α -adrenergic blockers, nonsteroidal antiandrogens, antidepressants, psychological therapy and physical therapy. This range of options to a large extent seems to reflect the fundamental lack of a deep understanding of the condition as it presents in many patients.

Introduction

The prostate is one of the male accessory glands that contributes to the male ejaculate by producing seminal fluid. In mice, removal of this organ reduces fertility (Pang et al., 1979). Our understanding of prostate development, maturation and anatomy has progressed steadily during the past century, but has been partially hindered by reliance on historical anatomical descriptions (Tisell and Salander, 1975; McNeal, 1980a,b; Timms, 1997). Lowsley's (1912) description of prostatic lobes has been replaced by the now widely accepted concept that the human prostate is better described as consisting of zones (McNeal, 1981) found within one discrete organ.

Recent advancements in computer technology allow organ structure to be visualized in 3-dimensions via digitized serial reconstruction. Three-dimensional reconstruction requires tracing, digitizing and axial alignment of identified objects (anatomical structures) within each section from a series of sequential sections. This provides a powerful tool for examining anatomical features, including those of the prostate. This technique has been particularly useful in understanding the complex pattern of ductal morphogenesis, an aspect that is extremely difficult to grasp when viewing 2-dimensional histological sections using a microscope (Timms et al., 1994; Timms, 1997). Additionally, the digital information used to reconstruct the prostatic features provides the basis for quantitative comparisons of experimental manipulations (Timms et al., 1994, 2005; vom Saal et al., 1997). Advanced prostatic imaging using magnetic resonance imaging (MRI) has also been used to build upon our knowledge of the prostate in both men (Bhavsar and Verma, 2014) and mice (McAuley et al., 2017), and will likely continue to provide insights into prostate homeostasis and pathogenesis.

The prostate is an exquisitely steroid hormone sensitive organ. Understanding hormone action during the different life stages of prostate organogenesis, puberty, and throughout adulthood and aging, is critical for understanding prostate anatomy and the different diseases of this organ. Indeed, the majority of men experience some form of prostate pathology during their lifetime. Our focus has been on examining the long-term impact of disruption of normal prostate development on structural and functional abnormalities related to specific types of prostate disease that often are not recognized until much later in life.

The prostate is important in fertility and general health. It is clinically significant because it often becomes diseased as evidenced by the frequency of prostatitis, benign prostatic hyperplasia, and prostate cancer. Prostate cancer (CaP) is one of the most common carcinomas in the Western world (Weir et al., 2003). Benign prostatic hyperplasia (BPH), which is sometimes referred to as benign prostatic hypertrophy, is a common condition beginning in middle age in men. Nearly half of middle-aged men can expect to develop urinary symptoms associated with BPH during their lifetime (Verhamme et al., 2002). Based on animal research, the potential exists for environmentally relevant concentrations of endocrine disrupting chemicals (EDCs) to impact human prostate pathogenesis (NTP-CERHR, 2008).

While there are no human data at this time to assess whether any aspect of prostate disease in men is related to developmental or adult exposures to EDCs, there is a marked similarity in effects in mice and humans due to exposure during sexual differentiation to high doses of the estrogenic drug diethylstilbestrol (DES). DES has been considered the prototypical EDC because there is a large literature about developmental exposure in humans and experimental animals. The conclusion from this literature is that the mouse is an important animal model for predicting the effects of developmental exposure to estrogenic chemicals and drugs in humans.

Historical Overview of the Prostate

Pathology of the prostate was attributed in 1685 by Samuel Collins to "indulgence in venery" that is, the pursuit of sexual pleasure. Collins recognized that prostate size was important with regard to urethral obstruction; this was also deliberated in 1769 by Giam-battista Morgagni (Zuckerman, 1936; Franks, 1954). Franks (1954) noted that Morgagni identified the site of origin of hyperplasia within the prostate and also examined the prevalence of this disease in aged men.

John Hunter observed in 1786 that the prostate (and other male accessory organs) underwent involution following castration. Zuckerman (1936) commented on the remarkable point that even though the implication of this observation would suggest that castration might serve as a treatment to relieve the effects of prostatic enlargement on urethral obstruction, which can be fatal, the implication of this observation was not grasped until many decades later. Castration as a treatment for enlargement of the prostate was finally proposed in the late part of the 19th century, after which it became the preferred method for treating the disease. This approach was soon abandoned because mortality associated with surgery was unacceptably high in that medical era. In addition, although it might seem surprising today, at the end of the nineteenth century there was still considerable controversy concerning the role of the testes in accessory reproductive organ function. At this time it was believed that any effects of the testes on organs such as the prostate were probably mediated via innervation, not secreted substances. This controversy is interesting in that it had been

reported in the mid 1800s that testicular grafts reversed the effects of castration in cockerels, which led to attempts to reverse impotence in aging men by means of xenografting testicular tissues. However, in 1927 procedures for extracting gonadal steroids were described, and testosterone was finally identified as the most potent of the testicular androgen in 1935. At this time, prostate growth in castrated male rats was routinely used as a bioassay for potency of testicular androgens (Burstein, 1955; Medvei, 1982).

Prostate Anatomy and Homology Among Species

Prostate Development and Anatomy

The prostate ducts begin forming as epithelial buds at about 70 days of gestation in humans, gestation day 16.5 in mice and 18.5 in rats (Takeda et al., 1986). These outgrowths begin as solid epithelial structures that branch during late fetal life in humans forming a compound tubulo-alveolar glandular structure (Marker et al., 2003). In mice, birth occurs within about 2 days of the beginning of prostate differentiation, while in rats birth occurs about 4 days after the initiation of gland genesis (Fig. 4). Widespread ductal branching occurs throughout infancy and adolescence. The adult structure is not achieved until approximately 7 weeks postnatally (Sugimura et al., 1986a,b,c). In humans, the pubertal increase in androgen secretion by the testes results in the prostatic glandular ducts forming an obvious lumen within the terminal acini. The epithelial lining becomes highly differentiated and structured, after which androgen-dependent secretory activity commences.

As shown in Fig. 1, the anatomy of the human prostate is described as consisting of zones (McNeal, 1981). The transition zone (TZ) is composed of short glandular ducts, which extend from the urethra above the intersection of the ejaculatory ducts. In the normal prostate the TZ consists of approximately 5% of prostate volume, but can increase in size significantly with age, mainly due to benign prostatic hyperplasia. The central zone (CZ) surrounds the transition zone just under the urinary bladder and is the zone through which the ejaculatory ducts pass and connect with the urethra. The CZ constitutes approximately 25% of the normal prostate and in general is not associated with benign prostatic hyperplasia. Another region that is less commonly described in men, is the anterior fibromuscular stroma. The peripheral zone (PZ) is located outside the posterior region of the central zone, and these ducts extend from the urethra below the intersection of the ejaculatory ducts (Lavoipierre, 2000). The PZ constitutes approximately 70% of the normal prostate volume and increases with age due primarily to the increased incidence of prostate cancer; the prostatic ducts in the PZ are the most prone to cancer, however the TZ has been reported to account for up to a quarter of prostate cancer cases (McNeal et al., 1988).

Interestingly, although BPH is commonly thought of as increased hyperplasia of the prostatic tissue, it is generally through increased proliferation of nodular growth and less so total prostatic proliferation. The structure of these nodules are spheroid, ranging in size from millimeters to centimeters in diameter. These nodular structures can be primarily glandular nodules (containing

Fig. 1 Diagrams of frontal and sagittal sections of the male urogenital complex showing the anatomical position of the adult prostate and associated structures. The prostatic zones are: central zone (CZ), peripheral zone (PZ), and transition zone (TZ). The anterior fibromuscular stroma (AFS) is also shown. From: Timms, B.G. (1997). *Anatomical perspectives of prostate development*. In: Naz, R. K. (ed.). *Prostate: Basic and clinical aspects*. New York: CRC Press.

epithelium and stroma) or stromal nodules containing primarily stromal cells (e.g., fibroblast-like cells or smooth muscle-like cells). Nodules emanating from the TZ may run parallel and surround the prostatic urethra effectively decreasing urethral compliance and urinary flow, leading of obstructive voiding disorder (OVD). As such, descriptors of BPH include glandular (or epithelial), stromal, and mixed (glandular and stromal) nodules. Although prostatic nodules have long been implicated as structural changes of the prostate, new developments in defining BPH have recently surfaced including the role of fibrosis and collagen deposition (Gharaee-Kermani et al., 2012, 2013; Ma et al., 2012; Bauman et al., 2014; Hao et al., 2016), ultimately changing urethral compliance and general structure of the prostate and urethra.

The ejaculatory ducts form from the embryonic Wolffian ducts during development. The ejaculatory ducts enter the prostatic urethra caudal and lateral to the site of the utricle (a “blind pouch”), which is the remnant of the Müllerian ducts as they merge and enter the posterior urogenital sinus (Fig. 2). The utricle becomes enclosed in the central zone of the prostate in men. Each ejaculatory duct (extensions of the vas deferens) merges with the ipsilateral seminal vesicle duct, which differentiates during the start of the 4th month of embryonic life in humans from the Wolffian duct proximal to the urogenital sinus. The ejaculatory ducts lead into the prostatic urethra next to an enlarged portion of the urethral crest known as the verumontanum. The verumontanum (also referred to as the colliculus seminalis or in latin, mountain ridge), is the amalgamation of three distinct structures: prostatic ducts, ejaculatory ducts, and the utricle (Fig. 1).

The prostatic urethra can be subdivided into a proximal segment (from bladder neck to verumontanum) and distal segment (from verumontanum to external sphincter). This forms a 35–40 degree angle from the horizontal edge at the verumontanum. The proximal urethra is surrounded by circular smooth muscle, which is commonly referred to as the preprostatic sphincter that is the autonomic component of the control of urination and also serves to stop retrograde ejaculation into the urinary bladder, as it is stimulated by alpha-adrenergic neurons to contract during ejaculation.

In contrast to men, the mouse prostatic complex consists of four paired sets of prostate lobes, tissues that immediately surround the prostatic urethra, as well as the ducts that connect the lobes to the urethra (Fig. 3A). The lobes are labeled for their anatomical locations and include: anterior prostate (AP), ventral prostate (VP), dorsal prostate (DP), and lateral prostate (LP). The morphology of the mouse prostate has been described in a series of papers by Sugimura et al. (1986a,b,c). The dorsal and lateral prostates intermingle and are commonly assessed together as the dorsal-lateral prostate or more simply the dorsolateral prostate. The AP, also known as the coagulating gland, lies in apposition to the ipsilateral seminal vesicle, and these are the most cranial of the prostatic

Fig. 2 Genital ducts prior to differentiation. Drawing of a human embryo at about 42 days of age with the upper half and left body wall cut away to demonstrate the gonads, associated Wolffian (mesonephric) and Müllerian (paramesonephric) ducts, and urogenital sinus (UGS). The prostate differentiates from the cranial UGS. The gut and its mesentery have been removed. Modified from: Allan, F.D. (1960). *Essentials of human embryology*. New York: Oxford University Press.

Fig. 3 Adult male mouse lower urinary tract. (A) The mouse has four paired prostatic lobes including: ventral prostate (VP), dorsal prostate (DP), lateral prostate (LP), and anterior prostate (AP) also known as the coagulating gland. Other structures include: urethra (U), urinary bladder (BLDR), ureters (UR), seminal vesicle (SV), and vas deferens (VD). (B) Schematic of a sagittal view of a adult male mouse lower urinary tract, prostatic complex, and urethra. The dorsal and lateral lobes are often grouped together as the dorsal-lateral prostate (DLP). Although the prostatic lobes surround the prostatic urethra, dorsal-lateral prostatic ducts connect to the urethra by entering into the rhabdosphincter (Rb) and run along the prostatic urethra from cranial to caudal ultimately entering the urethra near the verumontanum. These are a complex of tissues/ducts and not simply one duct/lobe. In contrast to the prostate, the seminal vesicles and ejaculatory ducts have one duct that connects to each SV and each vas deferens to the urethra. Caudal from the prostatic urethra, the membranous urethra enlarges in luminal volume. The lower left schematic is a transverse section of the prostatic urethra containing the periurethral space (PUS) which is made up of the urethral lumen (UL), prostatic tissues/ducts (PT), ejaculatory ducts (ED), SV ducts, all of which are surrounded by the Rb. The membranous urethra enlarges relative to the prostatic urethra and contains peri-urethral glands (PUG) surrounding the urethral lumen. The lower right schematic is a transverse section of the membranous urethra containing PUG surrounding the urethral lumen.

ducts. The DP ducts extend dorsally from the prostatic urethra, whereas the VP ducts extend ventrally, and LP ducts extend laterally from the prostatic urethra.

Within the prostate lobes prostatic fluids are produced that are a chief component of the seminal plasma. Prostatic secretions are primarily produced by the luminal cells within the prostate, which upon ejaculation, are transported to the urethra via the prostatic ducts (multiple ducts per prostate lobe) that enter through the rhabdosphincter and run parallel to the prostatic urethral lumen until entering the urethral lumen near the verumontanum (Nicholson and Ricke, 2011; Nicholson et al., 2012) (Fig. 3B). Prostatic glandular ducts extend from the prostatic urethra and branch into terminal ducts that are lined with pseudostratified columnar epithelium. In men, a continuous layer of basal cells underlies the luminal epithelium, while in rodents, basal cells are seemingly interspersed along the epithelial basement membrane (Hayward et al., 1998).

The prostatic epithelium and glandular ducts of the prostate are surrounded by varying degrees of smooth muscle. In humans, this layer of smooth muscle is much thicker than in rodents (Hayward et al., 1998), as such, the stroma to epithelium ratio is much higher in the human prostate compared to rodents. The function of this cell biological difference is unknown. However, in benign urinary diseases in men, alpha-adrenergic blockers, which act upon smooth muscle cells, are commonly used.

Evidence for Homology of the Rodent Dorsolateral and Human Prostate

Due to similarities and differences between rodents and human prostates, as well as the use of various mouse strains as the primary models of human disease, there has been interest in discerning whether zones of the human prostate are comparable to the different prostatic lobes in mice. In mice, prostate lobes can grow outwardly into the abdominal cavity without a restrictive fibromuscular “capsule” as found in humans. This lack of anatomical similarity has long been proposed as a reason for the mouse being an irrelevant functional model for the study of benign diseases like BPH, as decreased urinary function is considered unlikely. Contrasting the lobular prostate's role in disease, it has been proposed that experimental BPH in mice may be due to an increase in prostatic tissue and ducts surrounding the prostatic urethra (Nicholson et al., 2012), much like the new prostatic growth (i.e., BPH nodules) found in men, which can impinge upon the prostatic urethra decreasing urethral luminal area and hence cause an obstruction and urinary symptoms.

PROSTATE DEVELOPMENT IN RAT FETUSES

Fig. 4 Serial section reconstructions of the rat urogenital complex on gestation day (GD) 18, 19, 20, and 21, illustrating the stages of early prostate development. Prostate morphogenesis begins at GD 18 and by GD 19 the dorsal, ventral, lateral and dorsocranial (coagulating gland) buds are visible. On GD 21 (the day before birth), prostate budding from the UGS is essentially complete. *U*: urethra; *DP*: dorsal prostate; *LP*: lateral prostate; *VP*: ventral prostate; *CG*: coagulating [dorsocranial] gland; *SV*: seminal vesicle; *VD*: vas deferens. From: Timms, B.G., Peterson, R.E. and vom Saal, F.S. (2002). 2,3,7,8-Tetrachlorodibenzo-p-dioxin interacts with endogenous estradiol to disrupt prostate gland morphogenesis in male rat fetuses. *Toxicological Sciences* **67**, 264–274.

However, there remains controversy regarding whether the range of interspecies variations observed in the structure of the adult prostate gland reflects a diversity that makes it difficult to find suitable animal models for the study of human prostatic diseases (McNeal, 1990). Using a computer-assisted three-dimensional methodology to visualize the microanatomy of the developing prostate, we (Timms et al., 1994) have compared the ductal budding patterns during prostatic morphogenesis in rat, mouse, and human (Figs. 4 and 5). This reconstruction procedure revealed marked similarities in prostate development among rodents and humans.

When distinct species share comparable regulatory systems and common patterns of developing structures, this is taken as evidence that the structures are homologous between species, even though the final form may appear markedly different. A classic example is the wing of a bat, hand of a human, and fin of a dolphin. Thus, in evolutionary biology it is the structural and functional similarities in development, rather than appearance in adulthood, that is used as the basis for assessing whether structures such as the prostate are homologous between species. We proposed that the prostatic ducts that originate from similar regions of the urogenital sinus in rats, mice and humans are homologous structures (Timms et al., 1994). First, the dorsolateral ducts that develop in rodents show a pattern of budding similar to that in the human (Fig. 5). This finding is profound in that others (Price, 1963) observed that the relationship between prostate ductal openings into the urethra persists in the adult in the same relative position as found in the fetus. The major difference between rodents and humans is that, unlike rodents, the human prostate does not exhibit significant postnatal duct development in the ventral region of the developing urogenital sinus. The ventral region of the mouse and rat prostate may thus likely be less relevant for investigating factors that might impact the pathology of the human prostate, since ducts in this region are not found in men (Fig. 5C). To this end, it is the rodent dorsolateral prostate ducts that are homologous to ducts in the human prostate. Additionally, the anterior prostate ducts in the rodent, which are the most cranial ducts that develop from the fetal urogenital sinus, also appear homologous to the most dorsocranial (anterior prostate) ducts in humans.

Many animals, including dogs and cats, have prostates that show a similar developmental pattern to the peripheral zone in the human prostate, while the seminal vesicles and the central zone of the prostate are absent (McNeal, 1980a,b). The glandular tissue that forms the transition zone of the prostate, the zone that is prone to BPH in men, is thus absent in dogs (Hiraoka and Akimoto, 1987; Aumüller, 1989; McNeal, 1990). Nonetheless, adult male intact dogs can develop symptoms of BPH and have hyperplastic prostates. Moreover, experimentally, BPH can be induced in dogs by altering their hormonal milieu (Walsh, 1976; Coffey and Walsh, 1990; Johnston et al., 2000).

Homology also involves biochemical and molecular similarities, and a focus of ongoing research is on regulatory factors that mediate prostate development in humans and animal models (Adams et al., 2002; Thomson et al., 2002; Nicholson et al., 2015). Mesenchyme from the mouse prostate has been shown to produce the appropriate regulatory factors that were able to induce differentiation of human bladder transitional cell urothelium into prostatic epithelium expressing prostatic proteins (Abouseif et al., 1999), thus providing evidence for the similarity of regulatory factors required to identify homologous structures. As lobe-specific or zone-specific molecular determinants of development emerge, we will gain further insight into homology between species.

Environmental Impacts on Development of Prostate Ducts

Endocrine Disrupting Chemicals Alter Prostate Development

Endocrine disruptors such as dioxins, which act via the aryl hydrocarbon receptor (AhR) and also effect the estrogen-response pathway, have been implicated in prostate disease in a two-hit prostate disease model. We exposed fetal/neonatal male mice to

Region-Specific Ductal Morphogenesis of Mice and Men

Fig. 5 Panel A: Dorsal view of a newborn mouse urogenital sinus (UGS) reconstruction showing primarily the dorsal (D) prostatic outgrowths aligned with the paired prostatic sulci. The seminal vesicles and ejaculatory ducts have been removed from this reconstruction to clearly illustrate that the most cranial ducts form the long paired anterior prosstate (AP), also referred to as the coagulating glands. These glands extend and attach by a membrane to the anterior surface of the mouse seminal vesicles during subsequent development. Also shown are a few of the lateral (L) and ventral (V) prostatic ducts. The uterine is the midline structure in white. Panel B: Dorsal view of a 13-week male human fetus showing a similar paired pattern of prostatic duct outgrowths along the UGS. The most cranial dorsal prostatic outgrowths correspond to the equivalent anatomical location of the mouse coagulating glands. At these stages of fetal growth, the mouse and human prostate budding patterns demonstrate striking similarities. The uterine is the midline structure in white, and also shown are the seminal vesicles (SV). Panel C is a lateral view of the same human UGS. Modified from: vom Saal, F.S. and Timms, B.G. (1999). The role of natural and manmade estrogens in prostate development. In: Naz, R. K. (ed.) *Endocrine disruptors: Effects on male and female reproductive systems*. pp. 307–327, Boca Raton, FL: CRC Press.

2,3,7,8-tetrachlorodibenzodioxin (TCDD) (a dioxin; Hit #1), and later in adulthood changed their androgen and estrogen hormonal milieu (Hit #2) to mimic that of aging men (a decrease in androgen and an increase in free estrogen). The dioxin exposed mice had more clinically relevant aggressive BPH and lower urinary tract dysfunction compared to controls (Ricke et al., 2016).

Estrogen: Prostate Development and Adult Prostate Morphology

Many questions surround the safety of environmental chemicals with estrogenic activity regarding their ability to alter prostate development and subsequent susceptibility to disease later in adulthood, including prostate cancer and BPH (Zuckerman, 1936; Franks, 1954; Ricke et al., 2006, 2008; Nicholson et al., 2012). A basis for this supposition is that developmental biologists recognized that the region of the developing urogenital sinus just caudal to the bladder, from which the prostatic ducts emerge during fetal life, develops into a portion of the vagina in females. Thus, it is reasonable to venture that, since in the female the vagina is an estrogen-responsive organ, the male organ that develops from the same embryonic tissues, that is, the prostate, might also be estrogen responsive. This led to speculation that estrogens may play a role in regulating prostate organogenesis, subsequent function, and pathology.

In contrast to the notion that estrogens may play a role in normal prostate development, there are numerous reports that prenatal or neonatal exposure to high doses of estrogens, such as estrogenic endocrine disrupting chemicals (including the drug DES), dramatically inhibit the normal development of prostate ducts during fetal/neonatal life in rodents (Prins, 1997). In sharp contrast, more recently there have been studies concerning the stimulatory effects of endogenous estrogens, as well as very low doses of synthetic and natural estrogenic chemicals on development of the prostate. Taken together, these findings suggested the possibility that very low versus very high doses of estrogens could have opposite effects on prostate gland genesis, since non-monotonic dose-response relationships are a common feature of hormones (Vandenberg et al., 2012).

We found that male mouse fetuses exposed in utero to a very small increase (0.1 pg/mL) in free serum estradiol (i.e., within a physiological range) resulted in an increase in the number of fetal prostatic glandular buds (40% more) and overall prostate

size, which was associated with a permanent increase in the number of prostatic androgen receptors (Nonneman et al., 1992; vom Saal et al., 1997; Timms et al., 1999). There was also a significant expansion of the utricule in male mouse fetuses produced by the 0.1 pg/mL increase in free serum estradiol (vom Saal et al., 1997); the utricular portion of the Müllerian duct differentiates into the dorsocranial portion of the vagina in females (vom Saal et al., 1992).

Male mouse exposure to xenoestrogens during fetal life has also been demonstrated to affect prostate structure (Timms et al., 2005). Utilizing the computer assisted 3-D reconstruction method, we discovered that feeding pregnant mice a low 0.1 µg/kg/day dose of DES, the same low dose of the drug ethinylestradiol, or a 10 µg/kg/day dose of the estrogenic chemical bisphenol A (BPA) also stimulated additional prostate duct formation, as well as increased duct size in male mice examined on gestation day 19, just prior to parturition (Fig. 6). Specifically, these estrogens produced an increase in dorsal-lateral duct numbers and duct volume. Assessment of prostate proliferation revealed a twofold increase in cellular proliferation in the dorso-lateral ducts, particularly in cytokeratin-5 positive putative basal cells. Fetal estrogen exposure also lead to urethral constriction near the bladder neck as well as marked malformation in the verumontanum. The implications of these findings are that early-life xenoestrogen exposure may lead to the development of prostate and/or urethral abnormalities found later in adulthood. The hypothesis is that BPH, cancer, and other pathologies may be associated with abnormal ductal development during fetal life. Hence, a foundation for prostatic structural diseases found in adulthood may be explained in part by the hormone environment during gland genesis (Prins et al., 2017). In this regard, the research area of developmental origins of health and disease (DOHaD) is an active area of intense interest, and likely plays an important role in the prostate.

Exposure to supplemental estrogen (in combination with androgen) in adulthood has been related to hyperplasia of the prostate in dogs (DeKlerk et al., 1979), neoplasia in Noble rats (Leav et al., 1988) and mice, as well as inducing metastatic human prostate cancer in a tissue recombination model (Ricke et al., 2006, 2008). In C57Bl/6 male mice, elevation of either androgens or estrogens alone fails to produce dysplasia or prostatic intraepithelial neoplasia, but treatment with the combination of androgens and estrogens resulted in prostatic dysplasia and prostatic intraepithelial neoplasia (Ricke et al., 2008). Hormone manipulation appears to be strain specific, because in Noble rats, neoplastic tumors can be induced to form in the dorsolateral prostatic lobes, while Sprague Dawley rats typically do not develop any prostatic lesions (Noble, 1982; Leav et al., 1988, 1989; Ofner et al., 1992). Although fewer than 1% of Noble rats spontaneously develop adenocarcinoma of the prostate, treatment with a combination of low doses of

EFFECT OF ESTROGENIC CHEMICALS ON PROSTATE DUCT NUMBER AND SIZE IN GD 19 MALE CD-1 MOUSE FETUSES

Fig. 6 Three-dimensional serial section reconstruction of the urogenital sinus (UGS) from GD-19 mice exposed to low doses of estrogenic chemicals: diethylstilbestrol (DES), bisphenol A and ethinylestradiol (EE), during fetal development. The UGS depicted for each treatment was closest to the group mean for prostate duct number and size. All images are viewed from a left-lateral perspective. The upper images (Panel A) illustrate the differences in patterns of prostate ductal development following fetal exposure to these chemicals compared to control, untreated animals. There is a significant increase in both the total number of ducts in estrogen treated animals with a corresponding increase in overall prostate volume, particularly in the dorsal (DP) and lateral (LP) regions. The lower images (Panel B) show the marked alteration in the shape of the urethra (U) in the region of the bladder neck (BN), which is markedly constricted (*) in the mice exposed to the estrogenic chemicals, compared to controls. In addition, the region of the UGS associated with the development of the dorsolateral buds (the prostatic sulcus or colliculus—arrow) is enlarged, particularly by bisphenol A, compared to controls. Ventral prostate (VP). Bar = 100 µm. From: Timms, B.G., Howdeshell, K.L., Barton, L., et al. (2005). Estrogenic chemicals in plastic and oral contraceptives disrupt development of the mouse prostate and urethra. *Proceedings of the National Academy of Sciences* 102, 7014–7019.

testosterone and estradiol-17 β for 4 months or longer leads to multifocal prostatic epithelial dysplasia (Ho et al., 1992; Ofner et al., 1992), and results in the transition from dysplasia to neoplastic tumors in about 20% of treated males after ~10 months. Histo-pathological examination of prostates in Noble rats treated with androgen and estrogen showed that the tumors primarily involved glandular epithelium, and metastases after transplantation into new hosts revealed differentiated epithelial components (Noble, 1982). Prostatic neoplastic development occurs primarily in specific regions of the peripheral zone of the human prostate gland (McNeal and Bostwick, 1986). Dysplasia in the dorsolateral lobe of testosterone and estradiol treated Noble rats are nearly identical to the premalignant lesions described in the human gland.

Estrogens in conjunction with androgens have also been implicated in BPH/lower urinary tract dysfunction in male mice (Nicholson et al., 2012). Although prostate lobe growth increased and prostatic urethral area decreased leading to a subsequent bladder volume increase, it is likely that periurethral prostatic growth, which also significantly increased, was a major contributor to bladder enlargement. In addition to prostate proliferation, changes in prostatic urethral stiffness due to collagen deposition has also been proposed as a important prostatic structural change involved in disease progression of the prostate associated with other lower urinary tract symptoms or LUTS (Ma et al., 2012; Bauman et al., 2014; Hao et al., 2016).

Lastly, with regard to estrogens serving as ligands for receptors to promote disease progression, we have uncovered that many of the effects induced by estrogens in the development of prostate carcinogenesis and BPH/lower urinary tract dysfunction are mediated through estrogen receptor alpha. In mice hormonally induced to develop BPH or prostatic carcinogenesis, loss of estrogen receptor alpha, but not estrogen receptor beta, prevented pathogenesis for both diseases (Ricke et al., 2008; Nicholson et al., 2015). Furthermore, treatment of mice manifesting BPH with a selective estrogen receptor alpha antagonist prevented the development of BPH, whereas treatment with a selective estrogen receptor beta antagonist had no effect on preventing the development of BPH/lower urinary tract dysfunction (Nicholson et al., 2015). Overall, this suggests that estrogen receptor alpha is a key mediator of estrogen ligands involved in prostate disease initiation and progression.

Summary

The prostate is a sex accessory gland found in male mammals that provides secretions that aid in reproductive success. The prostate is a hormone regulated gland that can be dramatically affected by sex hormones and endocrine disrupting chemicals that we and others have found to be associated with prostate pathogenesis, both morphological and functional. The development of computer assisted 3-D technology has provided the opportunity to examine factors that alter prostate gland genesis during fetal life and the relationship of these changes to disease onset later in life using rodent models. These studies have revealed that, in contrast to some prior predictions, there are homologous regions of the prostate in the mouse, rat and human that make rodents useful models for the study of human prostate disease.

Acknowledgements

We thank Ms. Sally Griffith-Oh for her help in making figures of the mouse lower urinary tract, and Dr. Ellen Shapiro for providing the human tissue. Funding was provided by grants to WAR (U54 DK104310), CAR from NIEHS (ES-11549), BGT from EPA R-827403, and FVS from NIEHS (ES11283).

Prostate—Cell Biology and Secretion

Timothy D Gauntner and Gail S Prins, University of Illinois at Chicago, Chicago, IL, United States

Introduction

The prostate gland is an accessory sex organ that contributes secretions into the seminal fluid, which aids in sperm delivery and fertilization capacity. Two basic types of cells comprise the prostate gland: epithelial cells, which produce exocrine secretions, and stromal cells, which provide structure to the gland and help expel secretions into the urethra. Within these two broad categories of cells are numerous subtypes, the cellular, and molecular biology of which are detailed below. Although much of what is known about prostate cell biology has important implications for benign and malignant human prostatic disease, the ultimate role of the prostate gland and its constituent cells is to contribute secretions to the seminal fluid for enhancement of sperm delivery. The chemical constituents of these prostatic secretions and their physiologic roles are discussed in depth below.

Cell Biology

The cells of the prostate gland can be broadly classified into two types of cells: the parenchymal epithelial cells, which form the acini and ducts of the gland and secrete prostatic fluid, and the stromal cells, which envelop the acini and ducts to provide support and structure to the gland. The organization of these cell types within the human prostate is shown in Fig. 1.

Epithelial Cells

The acini and ducts, or parenchyma, of the prostate gland are formed by three phenotypically and functionally distinct lineages of epithelial cells—basal, luminal, and neuroendocrine cells (McNeal, 1998). Prostate epithelial cell stem cells, discussed in-depth below, reside within the basal cell layer. A fibro-muscular stroma envelops the glandular epithelium and helps to expel prostatic secretions into the urethra during ejaculation (McNeal, 1998).

Luminal epithelial cells

The exocrine product of prostate glands is produced by secretory luminal cells, which line the lumen of the glandular acini. Secretory cells are cuboidal or pseudo-columnar and rest on a layer of basal cells over the basement membrane. They secrete a variety of proteins and products into the lumen of the glands at the apex of the cell (Forest, 1979). Secretory luminal epithelial cells in the human prostate can be identified via immunohistochemical staining for prostate-specific antigen (PSA), prostatic acid phosphatase (PAP), androgen receptor (AR), the homeobox transcription factor NKX3.1, and cytokeratins CK8 and CK18

Fig. 1 Schematic depiction of the cell types and organization in the adult prostate gland. The epithelium has three types of differentiated cells; the secretory luminal cells, the basal cells along the basement membrane and a rare neuroendocrine cell. The rare stem cell resides in the basal compartment and upon asymmetric division, gives rise to a transient proliferative progenitor cell population that lineage commits to the differentiated cells. The stromal cells of the prostate include smooth muscle cells and fibroblasts.

(Wang et al., 2001; Sherwood et al., 1991; Bhatia-Gaur et al., 1999; Bonkhoff and Remberer, 1996; Epstein, 1993). Luminal cells express high levels of AR and depend on androgen signaling for their survival and secretory activity (Wright et al., 1996).

Basal epithelial cells

Basal cells are flat to cuboidal, nonsecretory epithelial cells. The human prostate has a continuous layer of basal cells with an approximate 1:1 ratio to secretory luminal cells. In other species, the basal cell layer is discontinuous and has an average ratio of 1:7 basal to secretory luminal cells (El-Alfy et al., 2000). Basal epithelial cells are distinguished from their luminal counterparts by expression of CK5, CK14, and the transcription factor p63, and by the absence of PSA or PAP expression (Wang et al., 2001; Sherwood et al., 1991; Bhatia-Gaur et al., 1999; Bonkhoff and Remberer, 1996; Epstein, 1993). Additionally, basal cells are mostly AR negative (Prins et al., 1991), although they may indirectly respond to circulating androgen via paracrine signaling with AR-expressing luminal cells or stromal cells. In addition to extracellular paracrine signaling, gap junction proteins between basal and luminal epithelial cells permit direct cytoplasmic signaling, suggesting that functions unique to each cell type are co-regulated by the other cell type. Furthermore, junction-like structures are found between cells in the basal layer, leading some to propose the existence of a blood-prostate barrier similar to that found in the testis (El-Alfy et al., 2000; Habermann et al., 2001). Such a barrier might explain the poor perfusion of systemically-administered antibiotics into the human prostate.

Neuroendocrine cells

Neuroendocrine cells represent a third, minor population of epithelial cells within the prostate gland. Although the functional significance of neuroendocrine cells is not well understood, they are known to secrete hormones and cell-signaling factors in response to neural stimulation. They are members of the diffuse amine precursor uptake and decarboxylation system, which is a part of the larger diffuse neuroendocrine system within the body. This classification, however, is merely based on histological and biochemical similarities among neuroendocrine cells found in various tissues throughout the body—cells of the diffuse neuroendocrine system do not necessarily share a common embryologic origin, nor are their functions coordinated by any known mechanism. Prostate neuroendocrine cells are found in the basal cell layer and exist in two distinct morphological variants: an open type, which has a single apical process that projects through the secretory cell layer to the glandular lumen, and a closed type, which has multiple dendritic processes that extend through the basal and luminal epithelial layers but do not reach the lumen. Neuroendocrine cells can be identified by their expression of chromogranin-A, synaptophysin, neuron-specific enolase, calcitonin, bombesin, and somatostatin (Bonkhoff et al., 1991; Abrahamsson et al., 2000). They do not express PSA or AR. While the precise physiologic role of neuroendocrine cells is unknown, they likely integrate neurohormonal signals to modulate development, proliferation, and secretory function of the prostate gland through paracrine mechanisms. Their embryologic origin is the subject of ongoing debate. The two morphological variants of neuroendocrine cells may even have different origins, as there is compelling evidence demonstrating both a neural crest origin of these cells, as well as an origin from a common prostate epithelial stem cell (Szczyrba et al., 2017).

Epithelial stem cells

Stem cells are responsible for repopulating the prostate epithelium throughout life. They reside in a stem cell niche within the basal epithelial layer, where they remain in a quiescent state until niche-derived signals stimulate their considerable proliferative potential. Much of what is known about prostate stem cells is derived from rodent models, however, knowledge of human prostate epithelial cells is rapidly increasing. The great impetus for studying prostate stem cell biology relates to the observation that cancer cells have many of the same characteristics as stem cells: the ability to divide nearly indefinitely, to resist apoptosis, to move within a tissue or even spread into other tissues, and acquisition of altered metabolic states, among others. Indeed, a central hypothesis in the fields of cancer and stem cell biology over the past decade is that stem cells are themselves oncogenic targets and tumor-initiating cells (Lang et al., 2009; Nikitin et al., 2007). Since stem cells are long-lived and quiescent, they may be susceptible to the accumulation of genetic mutations. Many scientists believe this is an important mechanism in prostate carcinogenesis.

There are three fundamental properties of a prostate stem cell: (1) slow growth rate/relative quiescence, (2) high replicative potential, and (3) ability to regenerate a prostate-like gland (Lang et al., 2009). During development of the prostate gland, the stem cells undergo relatively high proliferation in order to generate sufficient progeny to form the gland. In the adult gland, however, the stem cells remain in a relatively quiescent state due to both inherent growth-control mechanisms and cues from the niche. The signaling pathways that control this growth and the decisions to enter self-renewal are both autonomous, originating from the stem cells themselves, and extrinsic, originating from progenitor cells, stromal cells, and other cells within the niche. These pathways include the bone morphogenic peptide/transforming growth factor β (BMP/TGF β), wntless-integrated (Wnt)/ β catenin, fibroblast growth factor (FGF), Notch, Hedgehog, and Ephrin pathways (Prins and Putz, 2008).

At present, our knowledge of hierarchical relationships and regulatory pathways is largely based on adult stem cells, and it is possible that these relationships differ during early development (Xin et al., 2007; Leong et al., 2008; Goldstein et al., 2008; Ousset et al., 2012). Nonetheless, it is known that a precursor epithelial stem cell population is specified from the UGS endodermal lineage during molecular determination of the prostate prior to bud initiation. This process is programmed by a specific combination of WNTs, FGFs, other morphogens and prostate-specific transcription factors that commit the cells to a prostatic fate (Bieberich et al., 1996; Keil et al., 2012; Calderon-Gierszal et al., 2014). In the adult gland, this prostate-specified stem cell exists as a rare cell type that is relatively growth-quiescent and occasionally undergoes asymmetric cell division to give rise to either common or lineage-specific progenitor cell populations (linear versus bifurcated lineage models; see Fig. 2) (Kasper, 2008). These progenitor

Fig. 2 Linear and bifurcated models for human prostate epithelial cell hierarchy. (A) A prostate pluripotent stem cell undergoes asymmetric self-renewal to repopulate itself and generate a bipotent progenitor cell that transiently amplifies, forming late stage progenitor cells (aka intermediate cells) that lineage commitment to either basal or luminal epithelial cells. (B) A bifurcated model proposes that the bipotent progenitor cell gives rise to unipotent basal progenitor cells, unipotent luminal progenitors as well as a rare neuroendocrine cell type. The unipotent basal and luminal progenitor cells, upon several divisions, give rise to differentiated basal and luminal cell populations, respectively, under physiologic conditions. Adapted from Kasper, S. (2008). Exploring the origins of the normal prostate and prostate cancer stem cell. *Stem Cell Reviews* 4, 193–201.

cells are expanded by transient amplification prior to terminal differentiation, into basal, luminal, and neuroendocrine cell types. The stem cell niche, or microenvironment, provides signals to the stem cell and progenitor cells that dictate decisions for self-renewal, lineage commitment, and differentiation (Blum et al., 2010). This niche includes the mesenchyme/stromal and resident immune cells that communicate to stem cells through paracrine factors, as well as neighboring epithelial cells that communicate through gap junctions and cell adhesion molecules. It is important to note that prostate epithelial stem and early progenitor cells are AR-negative (Hu et al., 2011; Kasper, 2009; Huang et al., 2014) and are therefore not directly regulated by androgen action. As a result, any effects of androgens on prostate epithelial stem cell homeostasis and differentiation must be mediated through indirect actions via the stem cell niche, which includes AR⁺ stromal and luminal epithelial cells (Berry et al., 2008). Recent studies show that human prostate stem/progenitor cells express the estrogen receptors ER α , ER β , and G-protein estrogen receptor (GPER) and exhibit self-renewal responses to estrogens, implicating their involvement in the maintenance of the stem/progenitor pool (Hu et al., 2011; Prins et al., 2014). Thus, multiple signaling pathways directly and indirectly modulate the equilibrium between self-renewal and differentiation in prostate epithelial stem cell populations (Prins and Hu, 2013).

Epithelial stem cell niche

The human prostate stem cell niche is incompletely understood in terms of its anatomical location, histologic characteristics, cellular constituents, and hierarchical differentiation. In the adult human, the prostate stem cells reside among the basal epithelial layer of cells. The fate of these stem cells is governed by intrinsic and extrinsic factors. Intrinsic factors control stem cell self-renewal and differentiation in a cell-autonomous manner and include intracellular signaling molecules, chromatin remodeling enzymes, transcription factors, and noncoding RNA such as miRNA and piRNA (Zon, 2008). Although intrinsic factors ultimately determine whether a stem cell remains quiescent, undergoes symmetric self-renewal, or differentiates via asymmetric self-renewal or committed differentiation, a network of extrinsic factors impinges upon the intrinsic network to integrate the needs of the tissue in regulating stem cell niche dynamics. Extrinsic factors include circulating hormones, locally produced paracrine factors, cellular adhesion molecules, extracellular matrix (ECM) molecules and a host of other factors. With the exception of circulating hormones, these factors are products of cells within the stem cell niche.

Lineage hierarchy

There are two hypotheses about how prostate stem cells form differentiated luminal and basal epithelial cells. The first hypothesis is that a single multipotent stem cell, upon asymmetric cell division gives rise to a multipotent progenitor cell, which, upon division,

generates basal- or luminal-specific progenitor cells. These lineage-specific progenitor cells ultimately give rise to the fully differentiated epithelia. The second hypothesis states that there are two separate populations of unipotent prostate stem cells—basal stem cells and luminal stem cells. Each of these divides to form lineage-specific differentiated basal and luminal cells. A diagram of both lineage models is shown in [Fig. 2](#).

Stromal Cells

The prostatic stroma is predominantly composed of smooth muscle and fibroblast cells, with intermixed endothelial cells, blood vessels, lymphatic vessels, nerves, adipose cells, circulating immune cells, and bone-derived mesenchymal stem cells. The stroma as a whole is known to play important roles in the development, structure and function of the prostate gland ([Nemeth et al., 1997](#)). Nevertheless, the precise origin and function of individual types of stromal cells are largely unknown. To this end, recent research efforts in prostate cell biology have focused on elucidating the specific roles of various stromal cell types, including the role of the extracellular matrix (ECM), which is secreted by stromal cells. One striking feature of the stromal compartment is its ability to change cellular phenotype and composition of ECM in response to cues from the microenvironment. In the past, these alterations in stromal phenotype and ECM composition had been considered merely reactive changes; however, it is now widely believed that these stromal changes may play active roles in benign and malignant prostate diseases.

Smooth muscle cells

Smooth muscle cells are immunohistochemically defined by expression of α -smooth muscle actin, myosin, desmin, vinculin, and vimentin. These cells provide the mechanical means by which prostatic secretions are expelled during emission ([Hayward et al., 1996](#)). The distribution of smooth muscle cells varies between species, with rodent smooth muscle found strictly in a periacinar distribution and human smooth muscle found in the interductal stroma as well as periacinar locations. Prostatic smooth muscle cells consistently express nuclear AR. In the mature prostate, smooth muscle AR is believed to stimulate paracrine signaling in response to androgens, which helps maintain fully differentiated growth-quiescent epithelium ([Prins et al., 1991, 1992](#); [Cunha et al., 1996](#)).

Fibroblasts

Fibroblasts are α -smooth muscle actin-negative and vimentin-positive. Classically, fibroblasts have been thought to be the primary cells responsible for deposition of ECM, however, it is now known that smooth muscle cells also contribute to the ECM. Beyond their role in providing structural support to the prostate gland, fibroblasts also serve as immune system regulators and mediators of the wound-healing response.

Stromal-epithelial interactions

In addition to providing structural support and contractile function to the gland, the stroma plays a fundamental role in the development and homeostasis of the prostate. Developmentally, androgen receptor-positive urogenital sinus mesenchyme (UGM) is necessary and sufficient to induce formation of prostatic buds from the urogenital sinus epithelium (UGE) ([Cunha, 1972](#)). Thus, UGM is instructive toward the epithelium, translating cues from circulating hormones into paracrine factors that direct proliferation and morphological development of the UGE. In the adult gland, stromal-epithelial interactions are also important in homeostasis of the normal gland, as well as in development of benign and malignant pathology.

It is believed that aberrant growth with benign prostatic hyperplasia is driven, in part, through reawakening of the embryonic growth potential of prostatic stroma. Likewise, evidence clearly shows a critical role for the stroma in driving prostate cancer progression ([McNeal, 1983](#)). Malignant epithelial cells induce an altered phenotype in the neighboring stroma, which are referred to as cancer associated fibroblasts (CAFs). It should be noted, however, that in vivo CAFs are composed primarily of smooth muscle cells with a minor fibroblast population. Nevertheless, CAFs have an altered transcriptional program that upregulates secretory products and engages in an exchange of factors and molecules that promote altered metabolism, survival, growth, and proliferation within the tumor ([Adisetiyo et al., 2014](#)).

The regional variations in epithelial proliferation and apoptosis along the prostatic ducts are associated with differing stromal organization. In the rodent prostate, the distribution of fibroblasts and smooth muscle cells varies along the length of a duct. In the distal regions, there is a discontinuous layer of fibroblasts between the smooth muscle cells, which surround the gland, whereas the stroma surrounding the proximal duct has multiple continuous layers of smooth muscle with only a few rare fibroblasts interspersed ([Nemeth et al., 1997](#)). Stromal growth factor expression mirrors the differing stromal organization along the prostatic ducts and is the basis for the variations in epithelial proliferation ([Nemeth et al., 1997](#)). It appears that, in general, fibroblastic signaling promotes epithelial proliferation, whereas smooth muscle signaling promotes cell death.

Extracellular matrix

The extracellular matrix (ECM) is produced by stromal cells and provides structural support and shape to the prostate gland. Beyond mere scaffolding, however, the ECM modulates cellular function and behavior through biophysical and biochemical cues ([Montano and Bushman, 2017](#)). Macromolecules such as collagen, elastin, laminin, fibronectin, fibrin, and perlecan are secreted by stromal cells in specific abundances and ratios that vary by tissue microenvironment and developmental stage. For instance, the basement membrane that surrounds epithelial cells and separates them from the stroma predominantly includes type IV

collagen, laminin, and heparan sulfate proteoglycan. The composition of this basement membrane shifts from fetal development through adulthood. Different macromolecular compositions of ECM provide different physical cues such as stiffness, tensile strength and pH. These function as signals to regulate epithelial cell proliferation, adhesion, and apoptosis to maintain appropriate homeostasis. The ECM is a particularly important component of the stem cell niche, where it is one of several extrinsic factors that regulate stem cell self-renewal. The ECM is also thought to play a very important role in prostate cancer.

Prostatic Secretions

The Prostate Gland Contributes Secretions to the Seminal Plasma

The primary function of the sex accessory tissues, which include the prostate, seminal vesicles, bulbourethral glands and glands of Littre, is the production of seminal plasma, the nongamete portion of the semen. The seminal plasma serves as a buffered, nutrient-dense transport medium for sperm as they are deposited into the female genital tract. Although individual components augment the fertilizing capacity of sperm, seminal plasma substances are not required for mature spermatozoa to successfully fertilize the egg. With a pH of 7.2–7.8, seminal plasma is slightly alkaline and acts to neutralize the acidic environment of the vagina. Prostaglandins in seminal plasma stimulate contraction of smooth muscle along the female genital tract, helping to propel sperm to the egg. Additional substances include zinc and IgA, which have important bacteriostatic properties, as well as an array of prostatic proteins that help prevent autoagglutination of sperm. Altogether, prostate gland secretions account for 25% of the ejaculate, which totals about 1–6 mL in a human male. Important components of the seminal plasma that are secreted by the prostate gland are listed in [Table 1](#).

Role of Prostatic Secretions in Coagulation/Liquefaction

Semen coagulates and forms a gelatinous mass soon after ejaculation due to clotting factors produced by the seminal vesicles. Although analogous to blood coagulation, the seminal coagulation process has a unique biochemistry that does not involve prothrombin, fibrinogen or the hematologic clotting factors. Furthermore, the seminal coagulation process is not inhibited by heparin or sodium citrate. Prostate-derived proteolytic enzymes, including seminin, plasminogen activators, and prostate-specific antigen (PSA), liquefy the coagulated semen after 15–60 min. This liquefaction frees the sperm to advance up the female reproductive tract. Defective or absent secretion of these liquefying factors from the prostate is one cause of reduced male fertility.

Regulation of prostatic secretion

Hormonal

The production of seminal plasma, including the prostatic component, is under hormonal control and driven by circulating androgens, which are always present in normal males. In the prostate, circulating testosterone is taken up by prostate cells, converted to dihydrotestosterone (DHT) which binds to luminal cell AR, dimerizes, and translocates to the nucleus. Nuclear AR binds response elements on androgen-regulated genes, initiating gene transcription with subsequent translation of secretory proteins or enzymes whose products are secreted into seminal fluid.

Neural

Prostatic secretions are also under neural control ([Ventura et al., 2002](#)). Both the epithelial and stromal compartments in the prostate are innervated by the autonomic nervous system.

Table 1 Prostate-secreted components of human seminal plasma

<i>Component</i>	<i>Function</i>
Prostate-specific antigen (PSA)	Liquefaction of semen
Citric acid	Inhibit premature capacitation of sperm
Spermine	Enhance sperm motility; Immunosuppressive actions
Cholesterol	Stabilize sperm membrane
Prostatic acid phosphatase (PAP)	Unknown
Phospholipids	Stabilize sperm membrane
Prostaglandins	Enhance sperm motility; modulate cervical mucous; Immunosuppressive
Zinc	Stabilize chromatin within sperm head
<i>Immunoglobulins</i>	
IgG	Antimicrobial
IgA	Antimicrobial

Components of Prostatic Fluid

Zinc

The prostate gland has the highest concentration of zinc of any organ within the human body (Bertrand and Vladesco, 1921). Prostatic secretions are responsible for the high concentration of zinc in the seminal plasma, which at $140 \mu\text{g mL}^{-1}$ is nearly 100-fold higher than the serum zinc concentration (Eliasson, 1977). The precise physiologic role of such high concentrations of zinc in the prostate gland and the seminal plasma is unknown. Indeed, while the prostate has a multitude zinc-containing metalloenzymes, the observed concentration of zinc far exceeds the theoretical concentration that would be necessary for such enzymes. Within the seminal plasma, zinc serves to stabilize chromatin within the sperm head. It also binds to semenogelin I and II in the seminal plasma, which serves to regulate liquefaction (Heathcote and Washington, 1973; Fair and Wehner, 1976; Jonsson et al., 2005). Finally, zinc also functions as an antibacterial factor in both seminal plasma and nonejaculatory prostatic secretions, with in vitro studies demonstrating activity against an array of gram-positive and gram-negative bacteria.

Citric acid

Citrate is a potent binder of metal ions and is one of the major anions in human seminal plasma. The mean concentration of citrate in the ejaculate is 376 mg/dL, which is 500–1000 times higher than that in blood plasma. Its molar concentration (20 mM) is comparable to that of the divalent metals together, 13.6 mM (calcium 7 mM; magnesium 4.5 mM; zinc 2.1 mM). Seminal plasma citrate predominantly originates from the prostate with a 100-fold less concentration found in seminal vesicle secretions (Zaneveld and Tauber, 1981). The high levels of citrate have been linked to the decreased ability of prostatic mitochondria to oxidize citrate, which results in an imbalance between citrate production and oxidation (Costello and Franklin, 1989; Costello and Franklin, 1994). Kavanagh (1994) measured citrate and isocitrate levels and found the prostate to have a 33:1 ratio, whereas other tissues demonstrated 10:1 ratios. This finding suggests decreased aconitase activity as the reason behind such high citrate levels in prostatic secretions.

Sodium, potassium, calcium, magnesium and chloride

Although seminal plasma contains calcium and magnesium in higher concentrations than other body fluids, the relative contribution of the prostate to these levels has not been established. It is known, however, that the concentration of sodium, potassium, calcium, magnesium, and chloride within prostatic fluid varies between individuals and states of wellness or disease (Kavanagh, 1985). This is in part a passive response to varied levels of citrate secretion in prostatic fluid during states of disease.

Spermine

Polyamines are small, positively-charged organic molecules that have two or more primary amino groups. These molecules are found in all eukaryotic cells, where they have pleiotropic effects on a variety of physiologic processes including cell proliferation. Spermine, so named as a polyamine that was first discovered in semen, is present in seminal plasma at concentrations of 50–350 mg/dL and imparts a unique odor to semen. The prostate gland has the highest concentration of spermine in the human body and is the primary source of this polyamine in seminal plasma. The enzyme ornithine decarboxylase (ODC) is the rate-limiting enzyme in the synthesis of polyamines and spermine. The expression of ODC is increased in BPH tissue, which suggests a possible role for polyamines in the pathogenesis of this disease.

At physiologic pH, spermine has four positive charges that bind strongly to acidic or negatively charged molecules such as phosphate ions, nucleic acids, or phospholipids. Spermine is generated via a series of enzymatic reactions that use other polyamines as substrates, proceeding from ornithine to putrescine to spermidine to spermine. Spermine is oxidized enzymatically by diamine oxidase, which is found in the seminal plasma. The aldehyde products from this reaction are very reactive and toxic to both sperm and bacteria (Folk et al., 1980; Williams-Ashman et al., 1972). This is one reason why prolonged exposure of sperm to seminal plasma will reduce its fertilizing capacity.

Prostaglandins

In 1934, von Euler coined the term prostaglandins to describe the active components in seminal plasma in the assumption that they were produced by the prostate. Over 20 years later, Eliasson determined that the majority of prostaglandins originate from the seminal vesicles, with the prostate gland's contribution being minimal (Eliasson, 1959). Nevertheless, the name stands to this day. Prostaglandins are expressed throughout the body, but in humans the highest concentrations by far are found in the seminal vesicles. The seminal plasma contains 15 different prostaglandins at a concentration of $100\text{--}300 \mu\text{g mL}^{-1}$. Prostaglandins are 20-carbon hydroxyl fatty acids containing a cyclopentane ring and two side chains. They are classified into four major groups (A, B, E, and F) based on the structure of the cyclopentane ring and given a number based on the structure of the side chain (e.g., PGE₃).

The E group of prostaglandins predominates in the male reproductive tract, while the F group predominates in the female. Prostaglandins have a variety of potent proposed physiologic effects in the male and are involved in erection, ejaculation, sperm motility, and testicular and penile contractions. Additionally, seminal fluid prostaglandins deposited in the vagina affect cervical mucus, vaginal secretions, uterine contractions.

Cholesterol and lipids

The human prostate contributes to the lipid fraction of seminal plasma, which contains 185 mg/dL of total lipids, 103 mg/dL of cholesterol, and 83 mg/dL of phospholipids. The phospholipids have been further characterized as 44% sphingomyelin, 12.3% ethanolamine plasmalogen, and 11.2% phosphatidylserine. This ratio of cholesterol to phospholipid helps stabilize the sperm against temperature and environmental shock (White, 1976; Poulos and White, 1973).

Immunoglobulins

Immunoglobulins are found in the seminal plasma at levels lower than in blood. Specifically, IgG is measured from 7 to 22 mg/dL and IgA from 0 to 6 mg/dL. IgM has also been detected in the seminal plasma at very low levels (Gahankari and Golhar, 1993). Given the lower levels of immunoglobulins, it is theorized that these may simply be exudates, however, IgA has been localized more so to the bulbourethral glands and suggests an immunologic component to the bulbourethral gland function. IgG and IgA are likely secreted from the prostate (Rumke, 1974).

Acid phosphatase

Acid phosphatase activity is more than 200 times more abundant in the prostate than any other tissue. Prostatic acid phosphatase (PAP) is a 102 kD glycoprotein dimer with seminal plasma levels of $0.3\text{--}1\text{ g L}^{-1}$. The substrate for PAP in the seminal plasma may be phosphorylcholine phosphate, which is rapidly hydrolyzed by the enzyme. However, the physiologic significance of the high levels of PAP and their function are not well understood (Chu et al., 1977; Lowe and Trauzzi, 1993). Serum acid phosphatase concentration was once widely measured as biomarker for metastatic prostate cancer; however, this has been usurped the more sensitive and specific assay for prostate specific antigen (PSA).

Prostate specific antigen (PSA)

Prostate specific antigen is a 33 kD glycoprotein that acts as a serine protease and is produced almost exclusively in prostate epithelial cells (Watt et al., 1986). PSA is involved in lysing the ejaculatory clot with semenogelin as its substrate. The PSA gene (*hKLK3*) is a member of the kallikrein family of genes, which are all located on chromosome 19 (Yousef and Diamandis, 2003). Expression of PSA is dependent upon androgens. Clinically, PSA is used as an important serum marker for prostate cancer and prostate disease since its presence in the circulation indicates a breakdown in the epithelial/basement membrane barrier. Unfortunately, while PSA is organ-specific, it is not cancer-specific and is found in the serum of patients with BPH as well as prostatitis. PSA is found in seminal plasma in concentrations from $0.5\text{ to }5\text{ mg mL}^{-1}$ whereas, PSA in serum of men 50–80 years of age without prostate disease is 1000-fold less at $1.0\text{--}4.0\text{ ng mL}^{-1}$ (Catalona et al., 1991). The serum level of PSA in men with prostate cancer is generally elevated ($>4.0\text{ ng mL}^{-1}$), but not until its level is $>10\text{ ng mL}^{-1}$ does this measurement suggest specificity for prostate cancer. As prostate cancer cells remain AR-dependent, even in the absence of androgens, circulating levels of PSA in patients with metastatic disease can reach into the hundreds and monitoring levels over time can be a useful indicator of progression and relapse after treatment failure (Partin et al., 1990; Oesterling et al., 1988).

Introduction: Anatomy and Function of the Prostate Gland

The prostate gland is an accessory male reproductive organ, located at the base of the bladder, and surrounding the urethra. It produces prostatic secretions that contain zinc, citric acid, calcium, phosphates, and other enzymes essential for sperm health and motility. At ejaculation, semen passes through the ejaculatory ducts and mixes with secretions from the prostate gland (Fig. 1).

Prostatic fluids arise from the epithelial cells lining the ducts that are separated from surrounding stroma by a basement membrane. The epithelium consists of basal, neuroendocrine and secretory (luminal) cells and it is polarized so that the secretions arise at the luminal aspect of the epithelium including prostatic-specific antigen (PSA). Basally located epithelial cells secrete extracellular matrix (ECM) for the basement membrane and also include the stem and stem progenitor populations. The surrounding fibromuscular stroma consists of smooth muscle cells, fibroblasts, nerves, endothelial cells, immune cells, and blood vessels. The smooth muscle component provides contractility that is required when proteins are exuded from the glands (Fig. 2).

The prostate gland is divided into three anatomical zones in the human: the central (CZ), transition (TZ), peripheral (PZ), and anterior fibromuscular zones, with each zone having a unique morphology and physiology (Fig. 1). The zones of the prostate are especially relevant, as different prostatic diseases arise from different zones. In rodents the structure of the gland is slightly different and is divided in lobes: ventral, anterior, and dorsolateral.

Diseases of the Prostate Gland

The prostate is extremely prone to disease in older men, with the most common disorders being benign prostatic hyperplasia (BPH), prostatitis and prostate cancer. BPH is defined as the progressive hyperplastic growth of the stromal prostate cells, resulting in enlargement of the gland. Since the prostate surrounds the urethra, enlargement due to BPH restricts urethral flow and is often accompanied by debilitating low urinary tract symptoms (LUTS).

Prostatitis is defined as inflammation of the prostate. The majority of prostatitis cases are nonbacterial in origin (vs. nonbacterial) and are characterized by chronic discomfort and pain in the pelvic region. The condition of prostatitis can be chronic (chronic prostatitis/chronic pelvic pain syndrome (CP/CPPS)) and men with a history of CP/CPPS have an increased risk of prostate cancer (PC). It is thought that chronic inflammation can promote tumorigenesis as it does in other tumors types.

Prostate cancer is characterized by uncontrolled cellular proliferation, epithelial dedifferentiation, and a gradual loss of ductal architecture. It is a progressive disease where benign glands generate premalignant lesions that eventually become cancerous foci. Prostate cancer is relatively slow growing but remains a lethal disease that is one of the most common causes of cancer death in men.

Fig. 1 Anatomical zones of the prostate. The prostate consists of four anatomical zones; the central (CZ), peripheral (PZ), and transition (TZ) zones, and the anterior fibromuscular stroma (AFS).

Fig. 2 Distribution of cell types within the prostate. The prostate is a glandular organ, consisting of an epithelial and stromal component, separated by a basement membrane.

Benign Prostatic Hyperplasia (BPH)

The zones of the prostate in the human gland are notable because different prostatic diseases arise from different zones. The transition zone, which is ~15%–30% of the prostate gland, is the site where BPH most commonly arises. Much of the following text will refer to BPH in men because there are only a few animal models of BPH; dogs spontaneously develop BPH but rodents do not. Although rats and mice are frequently used as experimental models for BPH, the difference between the anatomy of the prostate in men and rodents is limiting.

Benign prostatic hyperplasia may be defined histologically as a hyperplasia of the epithelium, stroma, or both in the periurethral transition zone of the prostate. The complex of symptoms that is often attributable to men with BPH are collectively referred to as lower urinary tract symptoms (LUTS). LUTS include frequency of urination, urgency, urinary incontinence, waking up multiple times at night to void (nocturia), weakened urinary stream, straining to void, and a sense of incomplete emptying of the bladder. LUTS are not specific to nor exclusive of BPH and there are many other potential causes of LUTS beside BPH, such as urethral stricture disease, neurologic bladder dysfunction, malignancies (including bladder and advanced prostate cancer), amongst others. Nevertheless, the prevalence of BPH increases in aging men, and is estimated as the 4th most common condition affecting men aged over 50 years old. By 80 years of age approximately 80% of men will have BPH (Roehrborn, 2008).

The Etiology of BPH

Men may have histological evidence for BPH without any symptoms and the size of the prostate gland does not correlate with the severity of symptoms. Human BPH is focal with distinct nodules of hyperplasia within the gland (McNeal, 1984, 1985; Deklerk et al., 1979). Focal growth of transition zone nodules compresses the urethra resulting in urinary retention which is widely believed to be the fundamental cause of the profile of symptoms which comprise LUTS due to BPH. However it is too simplistic to consider hyperplasia as the sole underlying cause of BPH. Instead the etiology of BPH is thought to be related to two components: a static component caused by anatomical obstruction and enlargement of the prostate gland plus a dynamic component which relates to the smooth muscle tone. Therefore current pharmacotherapies for this condition aim to reduce the size or to reduce the smooth muscle tone of the prostate. Overall BPH is a progressive condition and the natural history of the disease is believed to occur in three phases: (i) pathological BPH when there is evidence of tissue proliferation but no LUTS symptoms (ii) clinical BPH when LUTS develop and (iii) progressive disease when LUTS symptoms progress.

Treatment of BPH

Unquestionably, there is a role for hormones in development of BPH. The prostate gland is an androgen dependent organ and, with other sex steroids such as estrogens, hormones are essential for the development and maintenance of the gland. However, BPH does not occur in eunuchs and for over 100 years, castration was shown to reduce prostate size and in some patients led to the improvement of urinary symptoms (White, 1895). Contemporary treatments to reduce prostate size address the need to block androgen signaling. The most successful approach has been to block conversion of androgen to the more potent 5 α reduced metabolite, dihydrotestosterone using 5 α -reductase inhibitors. Beginning with finasteride, 5 α -reductase inhibitors are commonly used for the medical management of BPH. 5 α -reductase inhibitors act predominantly to reduce the size of the prostate gland and thus symptomatic changes will typically occur after 3–6 months.

An alternative pharmacotherapy approach to the treatment of BPH is the use of α 1-adrenergic receptor antagonists (α 1-blockers) to relax the prostate muscle and improve clinical symptoms. α 1-blockers do not reduce prostate growth, but act to block the binding of noradrenaline released from the sympathetic nervous system to the α 1-adrenergic receptor, which induces contraction in the smooth muscle of the prostate and bladder neck. As the α 1-adrenergic receptor is also expressed in blood vessels, the first class of drugs were relatively nonspecific α 1-blockers already in use for the management of hypertension, such as Terazosin, Alfuzosin, and Doxazosin. More recently, specific α 1A-adrenergic receptor antagonists are commonly used. Sildosin and Tamsulosin are the α 1A-receptor subtype-specific antagonists available clinically, yet the clinical responses are similar to nonreceptor specific antagonists. There are currently five α 1-blockers clinically available for the treatment of BPH (alfuzosin, doxazosin, silodosin, tamsulosin, and terazosin) with similar clinical efficacy. The α 1-blockers act relatively quickly, with results generally seen in 1–2 weeks, and generally act on any size prostate gland (large or small), but will not significantly change volume or serum PSA.

PDE5 inhibitors (phosphodiesterase-5 inhibitors) were recently added to the Australian Medicines Handbook as a treatment option for BPH. PDE5 inhibitors were initially approved for the treatment of erectile dysfunction and there is little proof-of-mechanism data about their role within the prostate. Alterations in the nitric oxide/cGMP signaling pathway were linked to the pathogenesis of BPH. A comparative analysis of mRNA from tissue collected from patients with and without BPH found that expression of the nitric oxide synthase gene was significantly lower in BPH diagnosed patients. The reduction in expression of nitric oxide synthase was positively correlated with increasing age and prostate volume. Clinical trials involving the use of PDE5 inhibitors for the treatment of LUTS associated with BPH found reduction in IPSS score was negatively correlated with age (Gacci et al., 2012). This supports the hypothesis that BPH pathogenesis results in a decrease in nitrergic innervation, leading to an increase in smooth muscle tone, and reduced clinical efficacy of PDE5 inhibitors in older men.

If medical management of BPH fails then surgery may be required. Transurethral resection of the prostate (TURP) removes the obstructing tissue using a resectoscope. TURP remains the predominant surgical approach in managing BPH. However the use of medical based therapies, specifically the α 1-adrenergic receptor antagonists and the 5 α -reductase inhibitors, has dramatically changed the clinical management of BPH. The widespread use of inexpensive and effective medical treatments as a first line of treatment has moved surgical intervention for BPH to a second line therapy.

Overall BPH is a very common disorder of the prostate gland increasing with increasing age. The etiology involves two components: the static and dynamic component. Medical management of BPH involves both reduction of prostate growth (static) using 5 α -reductase inhibitors, and change in smooth muscle contractility (dynamic) using α 1-adrenergic receptor antagonists and PDE5i. These treatments have side effects and there is a need to better understand the etiology of BPH and understand why patient responses are variable. Eventually this will lead to better tailoring of treatment and precision in the management of patients for this, as for other, diseases.

Prostatitis: Inflammation of the Prostate Gland

Prostatitis is a common condition related to inflammation within the prostate gland. There are four main classes of prostatitis, as described by [Krieger et al. \(1999\)](#). 90%–95% of reported cases of prostatitis are defined as chronic pain and discomfort from the pelvic region. The etiology of chronic prostatitis/chronic pelvic pain syndrome (CP/CPPS) is largely unknown requiring a complex treatment strategy ([Thakkinstian et al., 2012](#)). Bacterial and acute inflammation occurs less often and is most commonly treated with antibiotics.

Despite the unknown etiology of most cases of prostatitis, there is a general awareness that chronic inflammation may predispose or lead to pathologies of the gland, including both BPH and malignancy. The hypothesis is that chronic prostatic inflammation causes tissue damage and continuous wound healing, leading to prostatic enlargement. Patients with chronic inflammation and benign prostatic hyperplasia (BPH) have larger prostate volumes, more severe lower urinary tract symptoms (LUTS) and a higher probability of acute urinary retention than their counterparts without inflammation. Interestingly, chronic inflammation might be a predictor of poor response to BPH medical treatment ([Gandaglia et al., 2013](#)).

Chronic inflammation is also implicated in prostate cancer, as it is in other types of solid tumors. Increased levels of inflammatory factors, arising from changes to the tumor microenvironment, are thought to promote tumor progression. The presence of tumor infiltrating lymphocytes (TILs) also has prognostic relevance, similar to other types of solid tumors. In a recent study the immunological microenvironment of primary tumor was strictly correlated with patient outcome; specifically, infiltration of different TIL populations could predict poor outcome in men with locally advanced disease who relapse after surgery and radiotherapy. More work is warranted on this topic since the evidence provides a strong rationale for immunological treatment of prostate cancer ([Nardone et al., 2016](#)).

Prostate Cancer (PC)

PC is the most common noncutaneous cancer in men and the second leading cause of cancer death, constituting a global public health challenge. Unlike benign disease, prostate cancers usually arise in the peripheral zone of the gland and some men will have both BPH and prostate cancer. PC is a relatively slow growing disease that usually takes many years to progress. Most men are diagnosed with early stage localized prostate cancer and either considered to be at low risk of progressing and go onto active surveillance, or at high risk of progressing, requiring active treatment (removal of gland at radical prostatectomy or radiotherapy). About 1/3rd of men treated are not cured, the tumor recurs and the disease becomes advanced and/or metastatic. Men with advanced disease typically undergo androgen deprivation therapy via medical castration that initially reduces tumor burden and symptoms, but castrate-resistant prostate cancer (CRPC) develops resulting in death ([Fig. 3](#)).

The Challenges of Diagnosis and Treatment

A definitive diagnosis of prostate cancer is based on pathology and is most frequently adenocarcinoma and less frequently neuroendocrine. For decades the pathology of adenocarcinomas has been reported using the Gleason pattern to assign a score. The Gleason grade is an important tool for prediction of patient outcome and in making decisions for treatment. The system has evolved over time firstly with the calculation of a total Gleason Score that was calculated from the sum of the first and second most common patterns reflecting the fact that prostate cancer is heterogenous. Subsequently and more recently the Gleason Grade Grouping system has further simplified the system to provide better prediction of biochemical relapse (see Review [Kim and Andriole, 2015](#); [Epstein et al., 2016](#)).

At initial diagnosis most men are diagnosed with localized disease and the risk of progressing to more advanced disease is evaluated by PSA level, abnormalities upon digital rectal examination and Gleason Grade of tumor in needle biopsies (cT-stage). Those men with low-risk tumors are typically recommended for active surveillance but those men with intermediate or aggressive

Fig. 3 Schematic of prostate cancer disease progression.

(high-risk) cancer are assigned to active treatment that commonly includes radical prostatectomy or radiotherapy. Men with neuroendocrine tumors are considered to be at high risk of progressing to advanced disease.

Although there is about a 95% 5 year survival for men with localized disease, some men will go on to progress to advanced disease. Since the seminal discoveries of Huggins (Huggins and Hodges, 1972) showing that prostate cancer is a hormone dependent cancer and relies upon androgens for growth, the universal standard of care is androgen deprivation therapy (ADT). ADT is effective when the tumors are castration sensitive, but inevitably the tumors become castration resistant and despite salvage therapies, these men will eventually succumb to their disease. Despite many years of scientific and clinical research, prostate cancer remains a lethal disease in 2017 and accounts for more than 25,000 deaths in the US each year. The challenges for treating men with localized disease and advanced disease are different and the clinical management and focus of research programs is varied.

For men with localized disease PSA screening, extended biopsy templates and enhanced imaging techniques have enhanced the ability to identify men with PC, but has also so increased over-detection of clinically insignificant disease. This potentially results in the over-treatment of men with tumors that were likely to remain indolent and hence the saying that some men will die with, but not of, their PC. The critical question here is to be able to identify and accurately predict at diagnosis, which tumors are likely to remain indolent (vs. those that will progress), so that over-treatment (and conversely under-treatment) is negligible.

There are important drawbacks to active surveillance. At diagnosis, it is possible to misclassify high-risk cancers and miss the “window of curability.” Up to 30% of men who meet eligibility criteria for active surveillance decide to undergo immediate surgery and RP, are reclassified with aggressive tumors on final pathology. During monitoring, repeated biopsies are a cost burden on the health system and pose risks to quality of life including septicaemia, rectal and urinary tract hemorrhage, urinary retention, haematospemia, anesthetic-complications, pain, anxiety and erectile dysfunction (Chang et al., 2013). A limited number of studies have attempted to identify gene signature of likely indolent versus aggressive tumors in men with moderate grade prostate cancer, but these are not in common clinical use and remain to be refined to achieve accuracy of prediction of patient outcome (Fraser et al., 2017) (Fig. 4).

For men who are at high risk of progressing to more advanced disease, surgery and radiotherapy are common treatments but if these fail, the disease requires further treatment. In 1940, Charles Huggins identified the role of androgens in prostate cancer progression and this discovery was a crucial breakthrough that established the principles of hormone suppressive therapy for advanced disease. The response to hormone withdrawal (androgen deprivation therapy, ADT) in men with castrate sensitive tumors is immediate and often dramatic, although the side effects are significant and the response is rarely sustained. The failure to remain responsive to ADT is because the tumors develop mechanisms to resist the systemic loss of hormone. One resistance mechanism

Fig. 4 A summary of steps in the progression of localized to advanced disease showing where some critical decision steps occur.

involves activation of local biosynthesis of androgens within the tumor itself thereby overcoming the loss of systemic androgens. Understanding how this happens and the need to block intratumoral androgen biosynthesis, led to development and use of Abiraterone to block CYP 17, 20 lyase enzymes that convert progestins to testosterone. (De Bono et al., 2011) Other mechanisms of resistance to ADT include progressive changes in androgen receptor signaling, such as AR gene amplification, AR gene mutations, hypersensitivity to androgens and altered expression of AR co-activators and co repressors. (Knudsen and Penning, 2010) The need to block progressive changes to AR signaling led to use of another 2nd line therapy, enzalutamide (Beer et al., 2014), that blocks the AR. Both Abiraterone and Enzalutamide are used in combination with chemotherapy for men who have failed conventional ADT treatment but the survival is extended by months and is not curative.

Tailoring Treatments for Patients With Prostate Cancer

Thus the need to find treatments for men who have (and are at high risk of) lethal PC remain an imperative for clinicians and scientists. Molecular subtyping of tumors from men with metastatic CRPC identified frequent aberrations of AR, ETS genes, TP53, and PTEN in about 40%–60% of cases (Robinson et al., 2015). Many genes and pathways changes were noted and about 89% of CRPC cases had clinically actionable aberrations, including 62.7% with aberrations in AR, 65% in other cancer-related genes. This information could impact on treatment decisions. Similar studies reported molecular subtyping of primary localized prostate cancers, although the overall burden of aberrations is lower than in CRPC tumors (Cancer Genome Atlas Research, 2015). Using this type of information where molecular changes are noted for individual (or groups) of patients, is crucial to determining how to tailor treatment to specific subsets of patients, as well as identifying markers of treatment response and resistance to therapies.

Whilst treating lethal disease as it emerges is a necessary approach, there has been a shift in thinking that maybe earlier treatments in men with high risk localized disease might give greater benefit rather than wait for incurable disease to occur. Known as upfront therapies, there are recent trials that suggest this approach may provide patient benefit. For example, in the trials known as STAMPEDE and CHAARTED both progression free survival and overall survival was improved when docetaxel chemotherapy was given in combination with androgen deprivation therapy rather than when ADT fails. In the STAMPEDE trial, six cycles of docetaxel at the beginning of ADT for metastatic prostate cancer resulted in significantly longer overall survival than that with ADT alone (Sweeney et al., 2015). Upfront therapies such as this might be an important option to consider for men who are fit enough to undergo chemotherapy when they have newly diagnosed metastatic prostate cancer and begin androgen deprivation therapy.

Summary

The prostate is a complex gland prone to disease especially in older men. Prostate cancer has received much attention in the lay, scientific and clinical arenas, but despite decades prostate cancer remains a lethal disease for some patients. BPH and prostatitis are also common conditions but do not generally receive the same degree of attention and there have been fewer research advances for patient benefit. With an aging population in many countries, there is an imperative and need to find curative options for men with benign and malignant prostate disease.

Glossary

Epithelium Cell layer that is commonly found lining glandular structures and mucosal surfaces. Mostly secretory in nature.

Fertilization The process of haploid sperm and egg forming a new diploid cell.

Mesonephros Excretory organ similar to the kidney active during fetal development that forms part of the male reproductive tract.

Development and Structure

The development of the seminal vesicle glands is testosterone dependent and follows a similar pattern in most mammals. The formation of the seminal vesicle glands occurs in parallel with the development of the mesonephros, a primitive excretory organ of the early embryo. The embryonic mesonephros consists of numerous tubules that form the urogenital ridge. Each tubule connects a vascular glomerulus at one end, and opens into the Wolffian excretory duct at the other. The cranial tubules and glomeruli of the Wolffian duct undergoes atrophy and the corporal section develops into the epididymis (Sadler, 2012). By the thirteenth week of development in the human an invagination forms in the caudal portion of the Wolffian duct close to the urogenital sinus, dividing it into the deferent duct and the ejaculatory duct. This invagination constitutes the earliest form of the seminal vesicle gland which is at first a straight tube that branches into numerous convoluted ducts later in development.

In rodents, the formation of the seminal vesicle glands begins at the end of gestation, around day 19. At this point in development the seminal vesicle gland epithelium increases in height and forms a lumen (Fig. 1). The density of granular endoplasmic reticulum in the epithelium, important for secretion, increases (Aumuller and Riva, 1992). These changes constitute early fetal preparations for the main adult secretory activity of the epithelium. In human embryos, seminal vesicles differentiation is completed by the seventh month of gestation.

Fully developed seminal vesicle glands are paired structures consisting of convoluted and curved tubular glands with numerous lateral projections located posterior to the prostate and urinary bladder, superior to the distal ureter, and posterior to the rectum (Fig. 1). Laterally, the ampulla of the vas deferens and the veins of the prostatic venous plexus lie along its medial margins. The principal cells of the seminal vesicle glands are slender columnar epithelium, containing numerous mitochondria and a well-developed rough-endoplasmic reticulum important for protein secretion. Basal cells of the seminal vesicle gland are small stellate cells with a compact cytoplasm and few organelles (Aumuller and Riva, 1992).

The growth, development, and differentiation of the seminal vesicle glands from birth to the onset of puberty is slow. Before birth the seminal vesicle gland epithelium is a hollow tube surrounded by a layer of mesenchyme. Following birth the epithelium undergoes dramatic growth and branching (Settle et al., 2001) (Fig. 1). Buds from the epithelium grow laterally into the

Fig. 1 Mouse seminal vesicle glands. Gross morphology of the male reproductive tract (i) showing the placement of the large seminal vesicle glands (SV; ii) above the bladder (B) and meeting at the juncture of the vas deferens (V). The relative size of the seminal vesicles is evident in comparison to the testicles (T) and tail of the epididymis (E). Photomicrographs showing the internal (iii, iv) and capsular (v) epithelium of the seminal vesicle gland at 10 $\times$ and 40 $\times$ magnifications. The columnar epithelium (purple) is evident against the dense seminal vesicle gland fluid (pink).

mesenchyme as systemic androgen concentration increases, the elongating buds bifurcate, and the epithelium folds upon itself. After puberty, maximal androgen levels provoke growth of the seminal vesicles that triggers functional differentiation of the secretory epithelium. Finally, the glands develop to form sac-like structures which, in humans, have a capacity to store a volume of about 3.4–4.5 mL (Aumuller and Riva, 1992).

In humans, the duct of the seminal vesicle and the vas deferens share a common ejaculatory duct that opens into the urethra (Hafez, 2000); however, the ejaculatory duct is not present in any of the domestic mammals, where each duct opens separately into the urethra (Setchell, 1991). Dogs and cats have no seminal vesicle glands, while boars are considered to have the largest seminal vesicle glands among domestic animals. In humans, there are some individual variations in size and storage capacity of the seminal vesicle glands; two to three ejaculations may deplete the seminal vesicle glands to such an extent that a refractory period of at least 2 days is required before the glands fully restore sufficient fluid for a normal ejaculate. Conversely, in the bull the seminal vesicle glands are capable of storing up to 50 mL of secretions, sufficient to provide fluid for up to a dozen ejaculates.

Secretion of Seminal Vesicles

The seminal vesicle glands are an androgen dependent organ that secretes a significant fraction of the fluid that eventually becomes semen (seminal fluid). In most species the major contribution to semen volume is provided by the seminal vesicle glands. For example, human seminal vesicle glands contribute between 70% and 85% of ejaculate volume, bull seminal vesicle glands produce approximately 50% of ejaculate volume, and in the mouse seminal vesicle glands produce approximately 90% of the ejaculate volume (Kierszenbaum and Tres, 2011). Seminal vesicle fluid is a thick, viscous, alkaline fluid, resulting in semen having a mild alkaline pH. The alkalinity of semen helps neutralize the acidic environment of the vagina to maintain sperm viability in the female reproductive tract.

Seminal vesicle gland secretions contain various proteins, enzymes, mucus, vitamins, amino acids, ions, minerals, flavins, and hormones. Seminal vesicle gland secretions are characterized by a high content of fructose. Fructose is the primary source of energy for spermatozoa within the ejaculate. Other carbohydrates, inositol, glucose, fucose, ribose and sorbitol are also present in small amounts in seminal vesicle gland secretions. The lipid hormone, prostaglandin is found in all accessory sex glands but have their highest concentration in the seminal vesicle glands. Four types of prostaglandin are present in seminal vesicle gland secretions; prostaglandin A, B, E, and F. The secretions of the seminal vesicle glands contain ions including high concentration potassium, lower concentration sodium, while chloride is almost absent. The role of these ions is unclear but may center on sperm motility or contraction of muscle in male and/or female reproductive tracts. Large scale proteomic studies have identified upwards of 2000 seminal vesicle derived proteins in humans (Duncan and Thompson, 2007). Proteins required for the coagulation and liquefaction of semen such as semenogelins I, II, and kallikrein are secreted from the seminal vesicle glands and prostate and are integral to the functionality of semen (Lilja et al., 1987). Seminal vesicle secretions of induced ovulatory species such as camelids (including the llama) contain specific ovulation-inducing factors like β -nerve growth factor (β -NGF), which acts at the level of the brain to induce ovulation (Tribulo et al., 2015).

It would seem that while the seminal vesicle glands secrete a complex fluid, the main role of this fluid is to facilitate sperm survival and transport through both male and female reproductive tracts to enable fertilization. However, the high number of compounds in seminal vesicle secretions may suggest secondary roles in communication between sire and dam at the time of conception.

Role of the Seminal Vesicle Gland in Reproduction

The primary role of the seminal vesicle gland is to produce a supportive fluid to maintain sperm viability and functionality during transport through the male reproductive tract at ejaculation and female reproductive tract to facilitate fertilization of the ovum. Seminal vesicle fluid is rich in energy substrates, buffering agents and antioxidants expressly for the purpose of maintaining the functional capacity of the sperm. As sperm utilize carbohydrate for their energy to traverse the female reproductive tract they produce large amounts of reactive oxygen intermediates which can potentially harm the valuable paternal DNA contained within the sperm nucleus. High concentrations of antioxidant present in seminal vesicle gland fluid help to reduce potential oxidative stress and subsequent DNA damage. A major role of seminal vesicle gland derived prostaglandins is smooth muscle contraction. It is surmised that prostaglandins in semen aid in sperm transport in both male and female reproductive tracts by stimulating contraction of the testicular capsule, seminiferous tubules, epididymis, vas deferens, cervix and uterine body (da Silva et al., 2016). As semen is a coagulatory fluid the process of liquefaction is a necessity to release sperm to become free swimming in the ejaculate. The process of liquefaction requires seminal vesicle gland derived proteases to allow sperm to pass through the cervix after vaginal deposition at coitus.

The role of seminal vesicle gland fluid may not be as simple as solely maintaining sperm viability and facilitating sperm transport. Invertebrates including mosquitoes, crickets and flies use seminal vesicle gland fluid as a means to alter reproductive characteristics in mated females. In mice, horses, pigs and humans, seminal vesicle gland fluid induces significant changes to the maternal cellular environment of the endometrium or cervix. Interestingly, seminal vesicle gland fluid is nearly indispensable in natural conception, however assisted reproductive technologies such as artificial insemination and in vitro fertilization prove that seminal vesicle gland fluid is not a requirement for fertilization or successful pregnancy outcomes. Nevertheless, evidence in

mice, cattle and women suggest exposure to seminal vesicle gland fluid may improve fertility and benefit pregnancy outcomes (Odhiambo et al., 2009, Bromfield et al., 2014, Tremellen et al., 2000).

While seminal vesicle gland fluid is no longer a requirement for fertilization due to new technologies it is interesting to consider its potential as a mediator of pregnancy success in a number of species.

Glossary

Aspermia A medical condition in which semen is not produced.

Asthenozoospermia A medical condition in which sperm has reduced motility (<40% sperm motility).

Azoospermia A medical condition in which the semen contains no sperm.

Cryptozoospermia A medical condition in which the semen contains very little sperm in the pellet after centrifugation.

Hemospermia A medical condition in which blood is found in the semen.

Hypogonadism A medical condition in which there is diminished gonad activity (the testes in males).

Oligozoospermia A medical condition in which the semen contains reduced sperm (<15 × 10⁶ spermatozoa/mL).

Prostatitis Inflammation of the prostate.

Seminal vesiculitis Inflammation of the seminal vesicles.

Abbreviations

FSH Follicle stimulating hormone

ICSI Intracytoplasmic sperm injection

LH Luteinizing hormone

LOH Late-onset hypogonadism

SV Seminal vesicle

SVCA Seminal vesicle adenocarcinoma

TESE Testicular sperm extraction

Basics of the Seminal Vesicle

The seminal vesicles (SVs) are a pair of male accessory reproductive glands, located posteroinferior to the urinary bladder. The SVs are derived from the mesonephric duct (Wolffian duct), and develop as branches of the vas deferens at the junction of the vas deferens and the urethra. Thus, the excretory ducts of the SVs join with the ampulla of the vas deferens and the ejaculatory ducts merge with the verumontanum of the prostatic urethra. At ejaculation, the emission of SV secretions occurs dominantly through sympathetic action. Although there are a few exceptions, such as canines and felines, almost all mammalian species have SVs of varying sizes. In adult mice, the normal size of the SV is 1.5–2 cm in length and 0.3–0.5 cm in diameter (**Fig. 1**). In adult humans, the normal size is 5–10 cm in length and 3–5 cm in diameter (**Fig. 2**). Generally, secretions from the SVs account for 50%–80% of the volume of ejaculated semen and contain ions (Na⁺, K⁺, Cl[−]), sugars (fructose, glucose), peptides (glutathione), and, above all, are highly concentrated in protein (**Mata, 1995**). SV secretions partly act as a protectant of sperm in the female reproductive tract (**Araki et al., 2015**), and SV removal can severely reduce fertility (**Kawano et al., 2014**) as well as the metabolism of the next generation (**Bromfield et al., 2014**). In this article, we introduce the structural SV, focusing on three topics: the epithelial cells of the SVs, the human SV, and SV-derived diseases.

Epithelial Cells of the Seminal Vesicles

The SVs consist of a single layer of secretory epithelial cells, and an outer layer of smooth muscle (**Fig. 3**). The epithelia is essentially simple columnar in character, and the SV lumen, with partial diverticula, foldings, or outpouchings, may cause resemblance to pseudostratified columnar epithelia (**Fig. 3**). The protein concentration in the SV lumen can reach 200 mg/mL, indicating the high performance of SV epithelial cells in secretion and dewatering.

The secretory machinery of the SV epithelia requires well-developed rough endoplasmic reticulum, Golgi apparatus, and secretory vesicles to accommodate the massive production and secretion of SV proteins. In fact, numerous rough endoplasmic reticulum

Fig. 4 Electron microscopic observation on an epithelial cell of mouse SV.

are a frequently observed characteristic of SV epithelial cells (**Fig. 4**). SV proteins aggregate easily, in order to aggregate the semen and form a copulatory plug; the experimental expression of SV proteins in *Escherichia coli* is difficult because of this propensity for aggregation. However, unaggregated proteins are required in the epithelia and male reproductive tract before ejaculation. It is likely that SV proteins are folded precisely in the endoplasmic reticulum.

Another mechanism behind the high concentration of proteins in the SV lumen may be dewatering. SV epithelial cells take up water and electrolytes (Levine and Kelly, 1980) and aquaporins are present in the apical and basolateral membranes of SV secretory cells (Brown et al., 1993). The secretory and dewatering functions of the SV epithelia enable the high concentration of proteins found in SV secretions, and furthermore, induce the multifunctional capability of seminal plasma (e.g., regulation of sperm motility, protection of sperm from the female immune system).

The Human Seminal Vesicle

The prostate is prone to serious tumors, and therefore this male accessory gland has been extensively studied. However, the SVs seldom develop such pathology, and when removed, do not impact viability. In fact, in the case of curative prostatectomy for prostate cancer, removal of the SVs is a standard procedure (see Fig. 2). As described above, the size of normal adult SV is 5–10 cm in length and 3–5 cm in diameter (Fig. 2). The average amount of semen ejaculated by normal healthy men ranges from 1.5 to 2.5 mL, and secretions from the SVs account for 50%–80% of the ejaculate. The physiological role of the SVs is not entirely known. Understanding of the sources of sperm components and the functions of the SVs has been enabled by the split ejaculation study. Mawson and Fischer (1953) collected ejaculates in three separate containers. They have assumed that the first fraction was a mixture of sperm, epididymal and prostatic secretions, and the second fraction was a mixture of prostatic and vesicular secretions. The third fraction was assumed to originate mainly in the SVs. While, semenogelin 1, a 52 kDa-protein expressed exclusively in the SVs, is a major component of the semen coagulum (Robert and Gagnon, 1999), and together with semenogelin 2, it inhibits sperm motility. Hydrolysis by the protease prostate-specific antigen induces the degradation of the coagulum, enabling the sperm to move (Yoshida et al., 2008). Therefore, clinical SV problems can be related to male infertility.

Obstructive Azoospermia, Cryptozoospermia, Oligozoospermia, Asthenozoospermia, and Aspermia Due to Seminal Vesicle Diseases

Azoospermia and aspermia are rarely caused by obstruction of ejaculatory ducts due to diseases of the SVs or prostate; however, it does occur in more than 5% of infertile patients (Modgil et al., 2016). Infertility case reports with semen analysis displaying cryptozoospermia or azoospermia, but normal spermatogenesis by testes histology, have been diagnosed with cystic dilatation of the SVs. It is assumed, in these cases, that the cause of the cryptozoospermia or azoospermia was partial or complete occlusion of the ejaculatory duct due to cystic dilatation of the SVs. Successful conception was achieved for one patient who underwent retrograde dilatation of the ejaculatory duct (Iwasaki et al., 1988).

Atrophy of the Seminal Vesicles Due to Hypogonadism

The SVs are androgen-dependent organs, and decreased androgen levels are accompanied by SV atrophy. This can result in “non-obstructive” azoospermia, aspermia, and oligozoospermia. Male hypogonadism is classified into two types: primary hypogonadism, in which the testis itself is impaired, and secondary hypogonadism, caused by defects in the hypothalamus or pituitary gland.

Primary hypogonadism: This is often a hypogonadotropic hypogonadism characterized by elevated FSH and LH in the blood and decreased testosterone. Primary hypogonadism is a symptom of Klinefelter syndrome, and also describes many azoospermia cases of unknown cause. Androgen deficiency symptoms are improved by testosterone replacement therapy, particularly decreased semen volume, and the atrophic SVs recover their function. However, azoospermia is not ameliorated. In this situation, sperm can be retrieved by microdissection-testicular sperm extraction (microdissection-TESE), enabling conception by intracytoplasmic sperm injection (ICSI).

Secondary hypogonadism: Secondary or hypogonadotropic hypogonadism is characterized by a decrease in blood FSH, LH, and testosterone. Typical diseases of secondary hypogonadism include Kallman syndrome and congenital gonadotropin deficiency. Proper hormone therapy can improve both the late-onset hypogonadisms (LOH) and spermatogenesis disorders with a high rate of success, particularly decreased semen volume. Although testosterone replacement therapy such as Testosterone enanthate is relatively inexpensive, simple, and effective against LOHs, it does not affect spermatogenesis. Combination therapy with recombinant human FSH (r-hFSH) and human chorionic gonadotropin (hCG), which is currently available as a self-injectable medication, has been successful in the treatment of hypogonadotropic hypogonadism. This therapy increases the testicular and seminal volumes, induces the appearance of sperm in ejaculate in azoospermia cases, returns seminal findings to normal levels, and enables natural conception.

Seminal Vesiculitis

Seminal vesiculitis, that is, inflammation of the SVs, is a rare disease that often occurs in combination with prostatitis. The main symptoms are hematospermia (blood in the semen) and lower abdominal and perineal pain. Patients often present with hematospermia without any other symptoms. Although the cause of seminal vesiculitis is not well understood, it often occurs through

nonspecific infection with tuberculosis or other atypical infections. One diagnosis method involves quantifying the leukocytes present in ejaculate. According to the World Health Organization (WHO) guideline, normal semen contains less than 1×10^6 leukocytes/mL (WHO, 2010). Moreover, it is possible to infer whether the leukocytes are from the SVs or prostate. As described above, the third fraction of ejaculated semen consists of mainly SV secretions. Therefore, analysis of the third fraction, through counting the leukocytes and obtaining bacterial cultures, can be useful for diagnosis of SV infections. However, a high leukocyte count in semen does not necessarily indicate seminal vesiculitis and/or prostatitis. Moreover, it is not clear whether a high semen leukocyte count leads to impaired spermatogenesis. Liu et al. used transurethral seminal vesiculoscopy for the diagnosis of seminal vesiculitis, and demonstrated that the dilation of SVs and retention of turbid solution by leukocytes in the SV secretions were effective for diagnosis (Liu et al., 2014). The ejaculatory ducts and SVs were visualized to confirm the diagnosis of seminal vesiculitis and to determine the cause of the disease.

Fragmented peptides from semenogelin 1 have antibacterial activity which is strictly zinc-dependent (Edström et al., 2008). Furthermore, abnormal expression of semenogelin 1 has been observed in the SV tissue of intractable seminal vesiculitis patients (Liu et al., 2016). Thus, study of semenogelin 1 and its fragmented peptides may help identify causes of urinary tract infection, and improve methods of sperm screening.

Adenocarcinoma of the Seminal Vesicles

The incidence of primary seminal vesicle adenocarcinoma (SVCA) is extremely low compared to prostate cancer: these are only 60 cases of SVCA reported in the global literature. SVCA tends to occur in patients over 50 years old. Diagnosis is typically delayed because there are no specific symptoms and no specific tumor markers, though some tumor markers have been suggested, such as serological cancer antigen 125, and cytokeratin subsets 7 and 20. A very rare case of primary mucinous adenocarcinoma arose from a seminal vesicle cyst, which was associated with an ectopic ureter opening and ipsilateral renal agenesis. In that case, the development of SVCA may have been due to chronic stimulation of the ectopic ureter's secretion (Lee et al., 2007).

Why is SVCA so rare compared to prostate cancer? In one study, the thymidine labeling index (TLI), which measures DNA amplification, of prostate adenocarcinomas averaged 0.90%, which was significantly higher than for either normal epithelium or the epithelium of nodular hyperplasia (Meyer et al., 1982). On the contrary, the TLI of SV epithelium averaged 0.02% (Meyer et al., 1982), suggesting that the proliferative rate of SV cells is quite low. This may account for the rarity of SVCA.

Seminal Vesicle—Secretion

John E Schjenken, David J Sharkey, and Sarah A Robertson, The University of Adelaide, Adelaide, SA, Australia

Introduction

The male accessory sex glands include the prostate, seminal vesicle, and bulbourethral glands. These secretory organs together produce seminal plasma, a viscous fluid with a mild alkaline pH which neutralizes the acidic environment of the vagina and contributes to maintenance of sperm viability following ejaculation. Seminal plasma has important roles in reproduction that are broadly conserved across mammalian species and even in invertebrates, despite differences between individual species in accessory gland structures, seminal plasma composition and biological actions (McGraw et al., 2015).

Seminal vesicles are the major contributing organ to seminal plasma. First described in 1521 by Berengario a Capri, they were originally and mistakenly regarded as a storage organ for semen. They are now recognized as a functional unit together with the ampulla of the deferent and ejaculatory ducts that contribute to producing the seminal fluid (Aumuller and Riva, 1992; Schjenken and Robertson, 2014). These glands are androgen dependent and form in parallel with the development of the mesonephros around the 13th week of development in the human and towards the end of gestation (day 19) in the mouse (Brandes, 1974). In humans, following birth and up until puberty the development of the seminal vesicle glands is slow, but with increased androgen levels around puberty, the glands expand in size and increase their secretory capacity (Aumuller and Riva, 1992).

The secretions of the seminal vesicle gland play a facilitating role in male reproductive biology, with the complex fluid containing factors which promote sperm survival and transport, and capacity to secure female reproductive investment and sire offspring. After intromission, seminal vesicle derived proteins stimulate physiological changes in the female reproductive tract to maximize the chances of reproductive success. Depending on the species, this can take the form of a physical structure called the “copulatory plug” that prevents sperm loss and block mating by other males. In invertebrates, seminal plasma factors act to promote egg release and block female receptivity to other males. In some mammals, seminal plasma agents also promote ovulation while in many others, the female immune response is suppressed from rejecting the foreign sperm and instead persuaded to promote immune tolerance of embryos and fetuses sired by the same but not other males. The extent to which seminal vesicle proteins are effective in executing these biological processes has an impact on the likelihood of conception, and also influences the developmental trajectory and phenotype of offspring (Schjenken and Robertson, 2014; Brandes, 1974).

The seminal vesicle thus supports a variety of important mechanisms to maximize the chances of the male successfully siring healthy offspring. This article provides an overview of the secretions of the seminal vesicle glands and their biological activity in promoting sperm viability and function, and other aspects of promoting male reproductive success. The focus is mainly on mammalian species, but it is important to acknowledge that seminal vesicle secretions exhibit important functions in a wide range of vertebrates and invertebrate species, whenever intromission at mating occurs (McGraw et al., 2015; Schjenken and Robertson, 2014).

Secretions of the Seminal Vesicle

The fluid secreted by the seminal vesicle is rich in a wide range of bioactive moieties ranging from inorganic salts and micronutrients such as potassium and zinc, carbohydrates particularly reducing sugars such as fructose, lipid derivatives including prostaglandins and phosphorylcholine, and a unique array of glycoproteins notably lactoferrin, proteinase inhibitors and cell–cell signaling molecules known as cytokines (McGraw et al., 2015). The factors secreted by the seminal vesicles have functional roles in semen coagulation, sperm motility and capacitation and female immune regulation.

There are limited studies aimed at assessing the proteomic composition of human seminal vesicle fluid, primarily due to difficulties associated with the collection of clinical samples. Some studies have utilized aspirated seminal vesicle fluid collected during surgery to identify the presence of a group of basic proteins termed seminal vesicle specific antigens (Lee et al., 1989; Rui et al., 1984). These proteins are produced by the glandular epithelium and are now identified as members of the Semenogelin family, which are amongst the most abundant seminal vesicle secreted proteins.

In rodents, these proteins play a crucial role in copulatory plug formation (Lee et al., 1989; Duncan and Thompson, 2007). Other copulatory plug proteins, including the seminal vesicle secretion 2 (SVS2) protein, fibronectin, lactoferrin, and kallikrein are also produced at high levels by the seminal vesicle (Kawano et al., 2014; Lilja et al., 1987). Transglutaminase IV is essential for normal plug formation in mice, and its deficiency leads to infertility despite normal sperm count, sperm motility, and reproductive morphology since without a plug, few sperm are retained in the female tract after mating (Dean, 2013). SVS2 has been shown to be essential for normal fertility in mice through a role in sustaining sperm survival in the uterus (Kawano et al., 2014).

Considered as markers of human seminal vesicle function by the World Health Organization, fructose and prostaglandins are secreted at high levels by the seminal vesicle (WHO, 2010). Fructose is the primary sugar produced by the seminal vesicles with the levels of fructose reflecting the rate of production of secretory exudate (WHO, 2010; Mann and Lutwak-Mann, 1976). Fructose is

consumed by sperm following ejaculation and is used as the primary source of energy by spermatozoa as they traverse the female tract (Gonzales, 2001).

Prostaglandins are present in the seminal plasma of most vertebrate species (Schjenken and Robertson, 2014; Gonzales, 2001). Prostaglandins are found in all accessory sex glands, but in human semen are predominantly derived from the seminal vesicles (Gerozissis et al., 1982). These hormones are thought to enhance sperm motility as well as play a role in immune regulation in the female reproductive tissues, with prostaglandins being present in the seminal plasma of a number of species (Schjenken and Robertson, 2014; Gonzales, 2001).

Other seminal vesicle secreted proteins, including MHS-5 and protein C inhibitor (PCI) have also been used to assess seminal vesicle function (Calderon et al., 1994; Kise et al., 2000). For example, PCI has been used as a marker of seminal vesicle obstruction or agenesis (Kise et al., 2000).

Similarities and Differences Between Species in Seminal Vesicle Biology

There is large variation in the size and structure of the male accessory sex glands between mammalian species, and the composition and balance of their secreted proteins and other bioactive factors. In most species the seminal vesicle are the major contributor to ejaculate volume (McGraw et al., 2015). For example in humans seminal vesicle secretions comprise between 70% and 85% of the ejaculate, while in mice the seminal vesicle glands contribute approximately 90% of the ejaculate (Kierszenbaum and Tres, 2011). In contrast, the most prominent accessory sex gland in boars are the bulbourethral glands, while canine and feline species appear to lack seminal vesicles altogether (McGraw et al., 2015). The extensive differences between even closely related species in accessory glands is consistent with the considerable variation seen in male sex organs more broadly. This is viewed as evidence of rapid evolution in these tissues and functional alignment with reproductive strategy. For example, polyandrous rodent species invest more resources and often evolve larger and more elaborate male reproductive organs than related species where between-male competition is lower (Eberhard, 2009).

Despite the broadly conserved function of seminal plasma constituents from insects to mammals, there is substantial variation in seminal vesicle fluid composition between species (McGraw et al., 2015; Poiani, 2006). For example, boar seminal vesicles secrete both fructose and citric acid which in the human, are made in both the prostate and seminal vesicle (Mann, 1964), while the BSP proteins which are produced in seminal vesicles in the bull and contribute to sperm capacitation and sperm storage are produced by the epididymis in mice and humans (Lefebvre et al., 2007; Suarez, 2008). In camels and likely other induced ovulatory species, seminal vesicle secreted beta nerve growth factor acts following coitus to stimulate ovulation (Ratto et al., 2012).

Function of Seminal Vesicle Secretions on Sperm Survival

A central function of seminal vesicle secretions is to support spermatozoa as they transit through the male genital tract and subsequently the female tract to fertilize the oocyte. This occurs through factors that provide nutrient and energy requirements, protect sperm from oxidative stress and immune destruction, enable capacitation, and facilitate storage when immediate fertilization is not possible.

One key sperm survival factor is fructose, produced by the seminal vesicles and present in high concentrations in male seminal fluid. Following ejaculation, motile spermatozoa utilize fructose as their primary energy source for metabolism and motility (Schoenfeld et al., 1979). For this reason, the concentration of fructose in human seminal fluid is used as a surrogate marker of seminal vesicle gland function, as recommended by WHO guidelines for the processing and evaluation of human semen (WHO, 2010).

Sperm motility is positively influenced by the presence of prostaglandins, particularly the 19-hydroxylated forms of prostaglandin E (19OH-PGE1 and 19OH-PGE2), which are present at extraordinarily high concentrations in human seminal fluid and produced predominantly by the seminal vesicles (Aitken and Kelly, 1985). Prostaglandins may assist in protecting the male gametes from oxidative stress and inflammatory damage. The abundance of antioxidants produced by the seminal vesicle glands also act to mitigate against potential damage to paternal DNA from oxidative stress. Additional substances indicated as able to stimulate sperm motility include potassium, magnesium, bicarbonate, and prolactin, all of which are secreted products of the seminal vesicle glands (Gonzales, 2001).

An important event to occur at ejaculation is coagulation, the process whereby ejaculated semen immediately forms a gelatinous state. This process is mediated largely by the cross-linking of the seminal vesicle produced proteins Semenogelin (SEMG) 1 and 2 (Yamasaki et al., 2017). Coagulation is thought to be important in ensuring prolonged contact of spermatozoa with other seminal fluid components, as well as in aiding the retention of seminal fluid in the female tract and preventing the premature capacitation of sperm. An additional role of coagulation is in transiently restricting sperm motility by trapping them in the gelatinous mesh network, a process believed to be mediated by a fragment of the degraded SEMGs, the seminal plasma motility inhibitor, SPMI (Yamasaki et al., 2017). Premature acquisition of fertilizing capacity outside of the female tract is prevented by the seminal vesicle proteins, seminal vesicle secretion (SVS) 2, 3, and 4 (Kawano et al., 2014). Some 20 min or so after ejaculation, coagulated seminal fluid undergoes the process of liquefaction, whereby seminal vesicle-derived proteases degrade SEMGs and their by-products (including SPMI).

Once sperm pass through the uterine cervix, they acquire the ability to fertilize the oocyte, through a maturation process known as capacitation. Capacitation confers to sperm both enhanced motility and the ability to undergo the acrosome reaction. Recent studies have identified soluble CD38 (sCD38), produced by the seminal vesicle gland and released into the seminal fluid, as a critical regulator of sperm capacitation in mice and humans (Kim et al., 2015a), mediating its effects through interacting with CD31 present on sperm.

Inorganic moieties released by the seminal vesicle that contribute to supporting sperm function include potassium, bicarbonate, magnesium, prolactin, ascorbic acid, and zinc ligands (Gonzales, 2001). Potassium, bicarbonate, magnesium and prolactin all act to enhance sperm motility (Gonzales, 2001) while ascorbic acid operates in association with antioxidant defenses to reduce injury mediated by oxygen radicals and preserve the functional competence of sperm (Lewis et al., 1997). Zinc ligands secreted by seminal vesicle fluid regulates chromatin stability by reducing sperm chromatin zinc content (Bjorn Dahl and Kvist, 1990).

Male to Female Signaling Factors Produced in the Seminal Vesicle

Male seminal fluid regulation of female reproductive physiology and behavior is well-described in the insect kingdom (Gillott, 2003). For instance in *Drosophila*, male factors stimulate egg release, induce antimicrobial protein synthesis, and influence brain function to decrease female receptivity to other males (Ram and Wolfner, 2007). Successful fertilization and transmission of the male germ line to the next generation depend on the male's capacity to induce an adequate response in the female. The female is an active participant in this exchange—the information provided in seminal fluid is subject to “cryptic female choice,” a process by which females interrogate the reproductive fitness of the prospective male partners and invest reproductive resources accordingly (Roldan et al., 1992). Substantial male resource investment is placed in promoting the male's chance of successful fertilization of females, and drives a high rate of evolution in male accessory gland function. This process ensures optimal female reproductive investment and maximal progeny fitness (Eberhard, 2009).

Less is known about the male to female communicating function of seminal fluid and its consequences in mammals, where seminal fluid has generally been considered to have one biological function—providing the male gametes to fertilize the oocyte at conception. However a wide range of studies now clearly demonstrate that seminal fluid activates female responses in humans, mice and other animals including pigs, dogs and sheep, and that the seminal vesicle is the source of the key signaling agents mediating this interaction (Gillott, 2003; Schjenken and Robertson, 2014).

A key function of the seminal vesicle immune-regulatory factors is to modulate the female immune response, so that foreign male histocompatibility antigens can be accommodated and not rejected. This suppresses generation of effector immunity against sperm antigens and induces the female immune system to tolerate the presence of male transplantation proteins, or “histocompatibility” antigens. Because these same histocompatibility antigens are also present on embryos fertilized by the male, the immune response to seminal fluid effectively “primes” the female immune response to maintain tolerance and facilitate survival of embryos sired by that male.

Seminal Vesicle Immune Regulatory Factors

Amongst the key factors that mediate immune regulatory function is transforming growth factor beta, which is synthesized in the seminal vesicles in a latent form and then becomes activated either when the accessory gland secretions mix at ejaculation (e.g., in the pig), or in the female reproductive tract following coitus (e.g., in human) (Robertson et al., 2002; Tremellen et al., 1998). The three isoforms of TGFB (TGFB1, TGFB2, and TGFB3) are produced by the seminal vesicle and released into the seminal plasma of mice (Tremellen et al., 1998), humans (Tremellen et al., 1998) and every mammalian species so far examined, at extremely high concentrations ranging from ~200–1000 ng/mL. This concentration is unmatched in any other biological fluid other than possibly colostrum, where potent immune-regulatory function is required to induce oral tolerance in infants (Robertson et al., 2002).

Additionally in humans, 19-OH PGE1 and 19-OH PGE2 are potent immune-regulatory seminal fluid factors, through direct effects on dendritic cells (Gerozissis et al., 1982). In mice, CD38 has been identified as a third key regulator of the female immune environment following coitus (Kim et al., 2015b) and it also acts to enhance sperm capacitation in humans (Kim et al., 2015a). Whether CD38 has a similar immune regulatory role in humans is not yet clear.

Actions of Seminal Vesicle Immune Regulatory Factors in Promoting Reproductive Success

In mammalian species, including rodents and humans, the permissive immune response to seminal fluid commences when seminal vesicle derived immune regulatory factors are deposited in the female tract at coitus. TGFB interacting with 19-OH PGE and other agents binds to receptors on cervical or uterine epithelial cells (depending on the species and site of seminal fluid deposition) and elicits an inflammation-like response within the female tissues. The seminal fluid contact induces dramatic changes in cytokine gene expression that cause rapid recruitment of immune cell populations into the local tissues.

This immune response has been extensively characterized in mice where seminal fluid exposure results in induction of maternal immune tolerance to paternal transplantation antigens later expressed by the developing fetus and placenta

(Robertson et al., 2009). Many of the cytokines released by epithelial cells lining the female tract also act to directly promote embryo development and facilitate successful implantation and robust placental development (Robertson and Sharkey, 2016). Some of the beneficial effects of seminal fluid exposure are mediated through the stimulation of an immune cell type known as regulatory T cells (Treg cells), which react with paternal transplantation antigens in seminal fluid and later expressed by the conceptus, ensuring optimal immune tolerance for pregnancy is established (Guerin et al., 2011).

Similar immune priming events are activated within the cervical tissues of women after the introduction of seminal fluid at coitus (Robertson and Sharkey, 2016). Early investigations into this response revealed an efflux of neutrophils into cervical mucus following donor insemination with whole semen (Pandya and Cohen, 1985; Thompson et al., 1992). Neutrophils recruited into the cervical lumen may be important for the clearance of non-fertilizing sperm and other cellular debris as well as for the prevention of infection by potentially harmful pathogens introduced at coitus. It was then demonstrated that vaginal intercourse initiates a similar response, extending into the epithelium and deeper stromal tissue of the ectocervix of periovulatory women (Sharkey et al., 2012a). The major cell types recruited into the cervical tissue were macrophages and dendritic cells, along with a smaller contingent of memory T cells. Leukocyte recruitment is regulated by seminal fluid induction of genes encoding cytokines including CSF2 (GM-CSF), IL6, and CXCL8. Importantly, seminal fluid contact was an absolute requirement for the initiation of the inflammatory response as no inflammatory response was observed in women who abstained from intercourse or when seminal fluid contact was prevented by the use of condoms (Sharkey et al., 2012a).

TGFB has been identified as the key mediator of male to female seminal fluid signaling in human (Sharkey et al., 2012b). In men, TGFB is produced mainly by the seminal vesicle and secreted into the seminal fluid at very high concentrations in a predominantly latent, inactive form. TGFB is then activated upon deposition into the female tract via mechanisms including the low pH of the vagina and endogenous protease activity. Once activated, seminal vesicle-derived TGFB induces expression of potent immune-regulatory and pro-tolerance genes CSF2 and IL6 within the cervical tissue (Sharkey et al., 2012b). Prostaglandins are also implicated as mediators of the postcoital inflammatory response in women through inducing the neutrophil regulator CXCL8 (Denison et al., 1999).

Impact of Seminal Vesicle Secretions on Offspring Phenotype

Whether a pregnancy is conceived in the presence of sufficient seminal fluid secretions may have a bearing not just on fertility, but on pregnancy outcome. Recent studies in mice show that if pregnancies are initiated in the absence of seminal vesicle secretions after surgical removal of the male seminal vesicle glands, fertility and fecundity is reduced and also the resultant offspring show signs of growth restriction and altered metabolic phenotype (Bromfield et al., 2014). This implies that the father's contribution to pregnancy goes far beyond the provision of male gametes at conception and that molecules carried by the male ejaculate contribute to fetal development and programming of lifelong health (Lane et al., 2014).

However, seminal plasma is not mandatory for pregnancy success, as pregnancies are initiated using assisted reproductive technologies like artificial insemination (AI) where seminal plasma is washed away, and in vitro fertilization (IVF) where conception may occur without any male contact. Rather, evidence suggests that the quality of pregnancy and health of offspring may be compromised if conception occurs in the absence of seminal plasma. Evidence for this can be seen in several species with recent experiments in mice and golden hamsters highlighting the importance of seminal vesicle secretions for reproductive outcomes (Bromfield et al., 2014; Sjoblom et al., 2005; Wong et al., 2007). In these studies, excision of the seminal vesicles profoundly affects fertility and health outcomes in offspring with reduced fertility, delayed embryo development, and evidence of metabolic dysfunction (Bromfield et al., 2014). The reduction in fertility in the absence of seminal vesicles can be partly explained by oxidative damage to sperm. However the detrimental programming effects are also attributed to a lack of priming by the seminal vesicle signaling agents, as embryos derived from females exposed to seminal vesicle fluid and transferred to females not exposed to seminal vesicle fluid exhibit similar phenotypes (Bromfield et al., 2014). Consistent with an impact of seminal vesicle secretions, excision of all accessory sex glands in the golden hamster leads to a similar reduction in offspring fitness to that observed in mice (Wong et al., 2007).

Further evidence for seminal vesicle secretions contributing to the quality of pregnancy and developmental programming are seen in other mouse studies. Exogenous TGFB administered at mating to boost seminal fluid can rescue pregnancy loss in abortion-prone CBA/J $\times$ DBA/2 mouse matings, and a mechanism involving Treg cells is demonstrated (Clark et al., 2008).

Seminal Vesicle Secretions and Pregnancy Disorders in Women

Seminal fluid contact prior to conception is associated with susceptibility to various pregnancy pathologies including preeclampsia and in utero growth restriction. Pregnancies conceived following longer periods of sexual cohabitation with the conceiving male partner are relatively protected from preeclampsia and in utero growth restriction. Strikingly, clinical studies show that a change in male partner or use of barrier methods of contraception elevates the risk of preeclampsia, implying that exposure to the conceiving partner's seminal fluid contributes to this protection (Kho et al., 2009).

Exposure to seminal plasma from the conceiving partner around the period of embryo transfer in women undergoing IVF treatment is demonstrated to improve conception rate (Crawford et al., 2015; Tremellen et al., 2000). While a direct causal link has been

demonstrated in humans between seminal vesicle immune regulatory molecules and the benefits of seminal fluid contact, it has been postulated that the mechanisms that link prepregnancy coital activity and improved pregnancy outcomes are associated with an immune priming response, consistent with the Treg cell response demonstrated in mice (Robertson and Sharkey, 2016).

Environmental Regulation of Seminal Vesicle Function

There is increasing evidence that environmental exposures can impact both male and female reproductive capacity and the health of offspring (Lane et al., 2014). Nutritional perturbations and exposure to environmental chemicals can all compromise the quality of the male ejaculate and appear to impart consequences for offspring. This may be caused by changes in genetic and epigenetic marks in sperm (Lane et al., 2014; Fullston et al., 2013; Rissman and Adli, 2014), but there is also a prospect of effects on the immune priming capacity of seminal fluid, and particularly the secretory capacity of the seminal vesicles and the composition of seminal plasma.

Very little is known about the impact of the paternal environment on the composition of seminal vesicle secretions. There are some studies which demonstrate variability amongst seminal vesicle derived components in the seminal plasma. In humans for example, seminal plasma TGFB varies considerably between individuals, correlating inversely with age and is markedly increased in individuals with chronic HIV infection (Sharkey et al., 2016; Kafka et al., 2012). Additionally, levels of the seminal vesicle marker fructose are positively correlated with BMI (Martini et al., 2010) while seminal plasma prostaglandin levels are related to sperm DNA fragmentation and infertility (Intasqui et al., 2016). There is also evidence of fluctuations within men over time in TGFB and other seminal plasma components (Sharkey et al., 2016, 2017). These studies imply that changing paternal environment including nutrition, chemical exposures and the reproductive tract microbiome can affect seminal vesicle secretions, but further studies are required to define the mechanisms through which this occurs.

Conclusions

The simplistic view that seminal plasma acts just as a transport medium for sperm is now redundant with studies demonstrating key roles for seminal plasma molecules to support sperm function prior to conception and to create a postcopulatory environment that influences fertilization, embryo and fetal development and the health of the offspring (Schjenken and Robertson, 2014). Amongst the accessory sex glands, the seminal vesicles are a major contributor to composition of seminal plasma in most species, including humans. Despite the critical role that seminal vesicle secretions play around the period of conception and throughout pregnancy, there is limited information on the secretome of the seminal vesicles and the specific contributions of the different seminal vesicle secreted molecules.

Studies into the secretory capacity of seminal fluid may identify environmental exposures that alter the composition of seminal vesicle secretions and thus impact male and female reproductive capacity. State of the art proteomic techniques to characterize the seminal vesicle secretome of various species are required to identify the key conserved factors in addition to the species specific factors that contribute to function. More detailed knowledge of how seminal vesicle secretions are regulated and their biological effects will advance understanding of this important area of biology and may reveal more key functions for this organ in male and female reproductive health.

Sex differentiation and growth of seminal vesicles (SVs) are highly dependent on androgen levels. In this context, the secretory activity of the seminal vesicles in men are dependent by the endogenous increase of serum testosterone. In a rat model it has been showed that the increase in serum testosterone or treatment with androgens was associated with greater secretory activity of the seminal vesicles and increased seminal vesicle weight (Higgins and Burchell, 1978). It is generally known that the seminal vesicles possess 5- α -reductase activity, which converts testosterone to dihydrotestosterone, the active hormone (Gonzales, 2001). The secretory activity of the seminal vesicle is also regulated by the nervous system and both the cholinergic and adrenergic neurons affect its function. Muscarinic stimulus (cholinergic) increases nitric oxide production (Gonzales, 2001). Seminal vesicle is a source of nitric oxide synthase in men and previous data showed that the increase in nitric oxide may be associate with better secretion of fructose by the gland (Ehren et al., 1997).

Since seminal vesicles are considered as androgen-dependent, their characteristics may be used as biological marker of androgenic activity. Gonzales has developed a method to assess the androgen activity at the reproductive tract level based on both the serum testosterone level and the corrected seminal fructose level under the basal and the post-clomiphene stimulation. Men received 100 mg clomiphene citrate daily for 5 days. The second blood and semen samples were obtained one day after the last administration of clomiphene. Levels of serum testosterone were more related to the corrected seminal fructose than to seminal fructose concentration. Seventy-one percent of subjects with low serum testosterone levels had low levels of corrected seminal fructose, whereas only 28% of the same subjects had low levels of seminal fructose (uncorrected fructose) (Gonzales and Villena, 2001). The results suggests that corrected seminal fructose may be used as a biological marker of androgen activity in the reproductive tract.

Based on these premises, corrected seminal fructose measurement may be considered as the best marker of seminal vesicle function (Gonzales, 2002). The combined measurement of the serum testosterone level and the level of corrected seminal fructose allows the diagnosis of hypoandrogenism and/or obstructive process at the reproductive tract (Gonzales, 2001). An increase in the serum testosterone after clomiphene stimulation without increase in the corrected or true corrected seminal fructose suggests an obstructive process at the reproductive tract level, whereas absence of increase in serum testosterone and corrected/true corrected seminal fructose levels may indicate hypogonadism (Gonzales, 2002).

The relationship between serum levels of testosterone and seminal fructose levels has been previously analyzed by Gonzales et al.

In fact, it can be found normal levels of serum testosterone and low values of seminal fructose in men with azoospermia due to obstruction of the ejaculatory ducts. It should be noted in fact that one third of azoospermia and severe oligozoospermia have an obstruction of the ejaculatory duct (Gonzales, 2002).

It should be also point out that about 10% of azoospermic subjects may have congenital absence of the seminal vesicles and vas deferens. In this case, the diagnostic criteria are: low seminal volume (<0.5 mL), low pH and low concentration of seminal fructose with normal serum FSH levels. Diagnosis is also possible through measuring the seminal level of the specific protein of the seminal vesicle (MHS-5) (Calderon et al., 1994). This protein is absent in agenesis of the seminal vesicle. This is another useful marker for agenesis of seminal vesicles and/or the vas deferens.

Despite that increased serum testosterone level is related to seminal vesicle function, treatment with high doses of testosterone propionate results in diminished levels of secretions of seminal vesicles and prostate, probably due to down regulation.

SVs are responsible for the production of ejaculate and the major component of this liquid are semenogelin I, Alkaline fluid, Fructose, Prostaglandins, Clotting factors.

The remaining volume of semen is made up of testicular spermatozoa, prostatic secretions and mucus from the bulbourethral gland (La Vignera et al., 2013; La Vignera et al., 2011).

Several evidences have demonstrated a close link between diabetes mellitus (DM) and seminal vesicles function. In particular, our previous study showed that SVs of infertile patients with type 2 DM and DN had particular characteristics on ultrasound, as increase in body antero-posterior diameter, fundus antero-posterior diameter and in fundus/body ratio. SV dysfunction is one of the factors thought to contribute to male infertility due to SV dysfunction may relay to inflammation (La Vignera et al., 2011b). In particular, the seminal vesicles of diabetic patients are characterized by reduced or absent modification of the anterior-posterior diameter (evaluated with ultrasound examination) after ejaculation; the same parameter in healthy men has an mean reduction of about 3–4 mm.

Considering the contribution of seminal vesicles to the total ejaculation volume, it is clear that from the endocrinological point of view, the differential diagnosis of the hypospermia (reduction of ejaculate volume <1.5 mL) concerns the following conditions: hypogonadism, obstruction of ejaculatory ducts and the retro-ejaculation (Roberts and Jarvi, 2009). In diabetic patients, these three conditions are frequent due to the high frequency of hypogonadism, male accessory gland infection and neuropathy (La Vignera et al. 2011a; Condorelli et al., 2014).

Take home messages

- Sex differentiation and growth of seminal vesicles (SVs) are highly dependent on androgen levels. In this context, the secretory activity of the seminal vesicles in men are dependent by the endogenous increase of serum testosterone;
- Corrected seminal fructose measurement may be considered as the best marker of seminal vesicle function;
- Several evidences have demonstrated a close link between diabetes mellitus (DM) and seminal vesicles function. In particular, our previous study showed that SVs of infertile patients with type 2 DM and DN had particular characteristics on ultrasound.

Glossary

Buck's fascia A fibrous fascia encircling the corpora cavernosa and corpus spongiosum. It is regarded as the deeper layer (hence its Latin term, *fascia penis profunda*), and sandwiches erection-related vasculature (the dorsal nerve, dorsal artery, deep dorsal vein, cavernosal veins, para-arterial veins, and lymphatic vessels) against the tunica albuginea. In addition, Buck's fascia is imbued with smooth muscle from the tunica dartos arising from within the scrotum.

Cavernosal vein A specific drainage vein of the corresponding corpus cavernosum via emissary veins; it spans the entire length of the penis except for the penile crus.

Colles' fascia A fibrous layer encircling Buck's fascia and is in continuity with the superficial perineal fascia caudally and to Scarpa's fascia of the abdomen cranially. It further reinforces the integrity of the penile structure and encompasses several superficial dorsal veins, nerves, arteries, and lymphatic vessels.

Corpora cavernosa Two of the three major cylinders which comprise the major erectile bodies of the penis, the corpora cavernosa contain endothelial-lined sinusoids beginning at the mid-glanular level and ending approximately 0.2–0.5 cm away from the ischial tuberosity.

Corpus spongiosum The third cylinder (the other two being the corpora cavernosa) which comprises the major erectile bodies of the penis. Like the corpora cavernosa, the corpus spongiosum contains endothelial-lined sinusoids; however, it also contains the urethra (where urine passes through). It is continuous with the glans penis distally and the prostate gland proximally.

Deep dorsal vein Located at the dorsal groove formed by the corpora cavernosa, the DDV is the common drainage vein of the corpora cavernosa (via emissary veins) and the corpus spongiosum (via circumflex vein).

Distal ligament Grouped from the dorsal outer longitudinal layer of the tunica and extending into the glans penis, the distal ligament acts as a trunk to buttress the glans penis.

Dorsal artery The final branch of the pudendal artery, the dorsal artery is positioned dorsally along the corpora cavernosa. It is the major supplier of blood to the glans penis.

Dorsal nerve Arises from the pudendal nerve to innervate the glans penis, prepuce, and penile skin layer, from which sexual pleasure is derived.

Erectile dysfunction Defined as the inability to either attain or maintain a rigid erection for satisfactory coitus.

Erection-related veins A catch-all term for those veins which are located between the tunica albuginea and Buck's fascia, called as such because these veins are responsible for venous drainage during erection.

Hypospadias A congenital abnormality in which the opening to the urethra (the urethral meatus) is on the underside of the glans penis (distal hypospadias) or (more rarely) nearer the scrotum (proximal hypospadias).

Os penis Refers to the penis bone present in most mammals; humans technically lack an *os penis* but do possess an *os penis* analog: the distal ligament.

Para-arterial veins The veins that sandwich the dorsal artery, para-arterial veins are classified as either *lateral* and *medial* in accordance with their anatomical location.

Penile dysmorphism General term to describe a penis with a deviated or deformed erectile shape. It may be further classified as of a dorsal, ventral, lateral, or combined type.

Penile fibroskeleton Term describing the fibrous collagen tissue which builds up an erection's bone-like rigidity; the major ingredients all possess same histology type and include the tunica albuginea, the distal ligament, the ischiocavernosus muscles, and the bulbospongiosus muscles.

Phimosis A condition in which the penile foreskin cannot be retracted to free the glans.

Tunica albuginea The coat surrounding the corpora cavernosa, the tunica albuginea is the deepest fascia and is composed of inner circular and outer longitudinal collagen fibers in organized arrays interlaced with elastic fibers that form an irregular, latticed network on which the collagen fibers rest.

Embryology of the Penis

Origin of the Gonadal Embryogenesis

In embryogenesis, the gonadal ridge appears at approximately the 5th week of gestation and gives rise to the gonadal cords whereby gender differentiation of the external genitalia occurs between the 7th and 17th weeks. The Y-chromosome directs male

differentiation through the SRY gene, which in turn triggers testicular development from the gonadal cords. Thereafter, endogenous androgens begin to secrete.

Origin of the Penile Relevant Structure

In the cloacal membrane, the caudal region comprises the endoderm and ectoderm, which forms the urethra from urogenital folds whereby the precursor of the external genitalia develops; meanwhile, the cranial region is occupied by mesenchymal mesoderm with which the genital tubercle develops. It subsequently develops into the corpora cavernosa and glans penis under the influence of endogenous androgens such as dihydrotestosterone. On the caudal membrane, the endodermal portion is thought to be tabularized from proximal to distal and forms the urethra; whereas the ectodermal portion forms the penile skin and prepuce.

Human Penile Structure

The Fibroskeleton of the Human Penis

In the entire human body, the penis is uniquely gifted in its capacity to fluctuate between a spongy softness and a bony rigidity. Its fibroskeleton design is indispensable for this variability and requires that the tunica albuginea surrounding the corpora cavernosa play a pivotal role. When cavernosal sinusoids are filled with fluid blood (Fig. 1A), the existence of relevant structures such as the ischiocavernosus muscle, the bulbospongiosus muscle, and the rigid distal ligament in the glans penis are integral for maintaining an erection; absent these structures, the rigidity would most certainly be compromised. The tunica albuginea has been consistently, albeit incorrectly, described as a single layer structure with a uniform circumferential thickness; it is in actuality a bi-layered structure with a 360 degrees inner circular and a 300 degrees outer longitudinal layer, and is the major contributor of the fibroskeleton (Fig. 1A). The thinner collagen bundle of the inner layer is arranged circumferentially and the coarser collagen fibers of the outer

Fig. 1 Schematic illustration of the fibroskeleton of the human penis. (A) The tunica albuginea of the corpora cavernosa is a bi-layered structure in which a 360 degrees complete inner circular layer, together with the intracavernosal pillars, contains and supports the sinusoids, which are removed in this illustration. The inner layer and the 300 degrees incomplete outer longitudinal layer are a continuation of ischiocavernosus and bulbospongiosus muscles, respectively. Both layers are composed of collagen bundles with a longitudinal and circular orientation, respectively. There is an absence of outer layer bundles at the region between the 5 and 7 o'clock positions where the corpora cavernosa are in close contact with the corpus spongiosum. Distally, they are grouped into the glans penis forming the distal ligament, located at the 12 o'clock position of the distal urethra. This structure is indispensable for supporting the glans penis. The median septum is incomplete with dorsal fenestration at the pendulous portion of the penis and is complete where the penile crura are formed. (B) Photo of a distal segment of human penis, lateral sagittal section, presents the left dorsal artery, urethral meatus, inelastic distal ligament (*os penis* analog) and cavernosal membrane, which were not discovered until the 1990s. (C) An amplified illustration of the fibroskeleton in the distal penis which is markedly extensible in length when erect. Note the tunica albuginea and intracavernosal pillars form the major relay structure of the penile fibroskeleton.

layer arrayed longitudinally and extend from the ischiocavernosus and bulbospongiosus muscles. Interestingly, the 360 degrees inner layer encircles a cavernosal membrane (Fig. 1B) to completely contain the erectile sinusoids and—together with the intra-cavernosal pillars—support the cavernosal sinusoids. This membrane protects the delicate sinusoids in much the same way that an amnion protects a fetus.

There is a paucity of outer layer bundles at the region between the clockwise 5 o'clock and 7 o'clock positions. It is here that two structures form; these structures, termed the ventral thickening, are a continuation of the left and right bulbospongiosus muscles, respectively. There is close contact of the corpora cavernosa with the corpus spongiosum between them (Fig. 1C). Between the 11 and 1 o'clock positions on the dorsal aspect, there is also a dorsal thickening of the outer longitudinal tunica, a radiating aspect of the bilateral ischiocavernosus muscles. The continuation of the outer longitudinal layer of the tunica, located at the 12 o'clock position of the distal urethra, is grouped into the glans penis to form the distal ligament—an *os penis* analog. This structure is arranged centrally and acts as a trunk of the glans penis to maintain patency of the distal urethra and preserve the range of ejaculation. At the pendulous portion of the penis the median septum exhibits dorsal fenestration; the extent of fenestration is commensurate with the quantity of the intracavernosal pillars. In the distal penis, the pillars are most numerous where the septum is most incomplete, to allow for tensile capability.

Overall, in the human penis, the components of the skeletal muscles include the ischiocavernosus and bulbospongiosus muscles and their continuing fibroskeleton. The distribution of the tunica albuginea is, however, singularly dependent upon specific anatomical parts in accordance with which a functional requirement exists—take the corpora cavernosa and corpus spongiosum, for instance. Thus, the skeletal ischiocavernosus muscle, bulbospongiosus muscle, and a bi-layered tunica albuginea support and encircle the corpora cavernosa. A mono-layered tunica albuginea contains the corpus spongiosum while the skeletal bulbospongiosus muscle partially encloses it, thereby allowing ejaculation despite erectile rigidity (since tumescence, as opposed to rigidity, is conserved). This is a result of the paucity of the outer longitudinal layer. In the glans penis, however, the bony distal ligament is entrapped by the smooth muscle sinusoids and serves as a kind of trunk, allowing the glans to protect the reflexogenic erectile mechanism—thus rendering it essential to coitus.

Paired Corpora Cavernosa of the Human Penis

Among the three cylinders in the human penis, the most incredible is the paired corpora cavernosa, which contain endothelial-lined sinusoids beginning at the mid-glanular level (Fig. 2A) and ending approximately 0.2–0.5 cm away from the ischial tuberosity via a

Fig. 2 Schematic illustration of a three-dimensional view of the human penis. (A) *Lateral aspect*. The penis leans upon the suspensory ligament which is an extension of the linea alba. It is capped by the glans penis. Proximally, the corpus spongiosum is held by the bulbospongiosus muscle, in which the fibers are mostly transverse. The corpora cavernosa are surrounded by the tunica albuginea, which is a bi-layered structure (an inner circular and an outer longitudinal layer with multiple sublayers). The intracavernosal pillars (which may be considerably larger distally) are a continuation of the inner circular layer. The corpus cavernosum is entrapped in the ischiocavernosus muscle with the muscle fiber aligned in the longitudinal direction. (B) *Medial aspect*. The distal ligament is aggregated from the collagen bundles of the outer longitudinal layer of the tunica albuginea. It is an inelastic fibrous structure which forms the trunk of the glans penis. The incomplete septum is dorsally fenestrated. The corpus spongiosum contains the urethra. (C) *Ventral aspect*. The three-dimensional structure of the human penis is evident. The ischiocavernosus muscle is paired and situated at the lateral boundary of the perineum. Each segment covers its ipsilateral penile crus. Meanwhile the anterior fibers of the bulbospongiosus muscle partially spread out to encircle the corpus cavernosum and mostly insert into the ventral thickening of the tunica.

skeleton-fibrous ligament. On the pendulous (visible) portion of the penis, the twin corpora communicate freely via a dorsally-fenestrated, incomplete septum; the septum becomes complete nearer the body and toward the penile crura, which are surrounded by ischiocavernosus muscle and relevant tendinous tissues. Elastic-rich intracavernosal pillars run between the 10 and 2 o'clock to 6 o'clock positions; the number of pillars increases distally and is inversely proportional to the completeness of the septum (Fig. 2B). At the beginning portion of each crus lies Kobelt's bulb of the cavernosum, which subsequently tapers toward the proximal end (Fig. 2C). Moreover, the corpora cavernosa are distally very near but proximally divergent, each eventually terminating near its respective ischial tuberosity.

Within the corpora cavernosa, the cavernosal sinusoids are highly trabeculated with fibroelastic, smooth muscle fibers and fibroblast. These fibers are thicker and stronger at the periphery of the cavernosum than at the center, which features diametrically larger cavernous spaces. Within each of the compartments formed by this crisscrossed pattern, numerous blood vessels and nerves flourish. These spaces are lined by flattened endothelial cells similar to those lining blood vessels. The cavernosal sinusoids are supplied with blood from the cavernosal and helicine arteries, which drain into the sinusoidal space via the venules starting at the peripheral sinusoids beneath the tunica albuginea. Free-flowing blood throughout the sinusoidal spaces then converge to emissary veins, which pass blood obliquely via the inner circular and outer longitudinal tunica to the deep dorsal vein (DDV), the cavernosal veins (CVs), and PAVs, which eventually drain to the larger circular system. Absent any veno-occlusive dysfunction, the corpora cavernosa is the most ideal milieu in the entire human body to test Pascal's law. The law states that pressure applied to any part of an enclosed fluid at rest is transmitted undiminished to every portion of the fluid and to the walls of the containing vessel.

Singular Corpus Spongiosum and Glans Penis

The third cylinder of the penis is the singular corpus spongiosum, which, like its counterparts, the two corpora cavernosa, also contains endothelial-lined sinusoids. Unlike the corpora cavernosa, however, the corpus spongiosum hosts the urethra, where it dilates to form the urethral bulb nearby Kobelt's bulb of the spongiosum proximally. The corpus spongiosum is ventral relative to paired corpora cavernosa, and it connects the glans penis distally and the prostate gland proximally (Fig. 2B). Also in contrast to the corpora cavernosa, the corpus spongiosum lacks an outer longitudinal tunica or intracavernosal pillars, thereby assuring low pressure during an erection. This design, consequently, allows for an extraordinarily cushioned milieu for the propulsion of urine and semen. The spongiosum body is full of coarser elastic fiber and does not contribute to penile erectile rigidity but does contribute significantly to penile swelling (tumescence). At the point, it lies intimately against the inferior fascia of the urogenital diaphragm, from which it receives a fibrous investment. The urethra enters the bulb closer to the upper than to the lower surface. On the lower surface, there is a median sulcus, from which a thin fibrous septum projects into the substance of the bulb and divides it imperfectly into two lateral lobes (Fig. 2C).

The glans penis is a conical vascular body forming the extremity of the penis and covered by a stratified squamous epithelium, and at its end is the urethral meatus, where a slit-like vertical external urethral orifice presents. It forms a round projecting border at its proximal limit; this border is called the *corona glandis* and overhangs the retrocoronal sulcus. The glans is buttressed with a distal ligament, whereby a surge in pressure can be transmitted and ejaculate emitted during coitus despite being hindered by vaginal wall compression. Immediately beneath the subcutaneous layer, there is a strong perisinusoidal fibroelastic shell which is responsible for its resilient nature and cushioning function, both being critical for coitus. The elastic fibers are thicker and denser in the glans sinusoids than elsewhere in the entire penis.

In summary, the sinusoids are specific to their respective containers: the corpora cavernosa, the corpus spongiosum and the glans penis; the conventional medical knowledge regarding the spongiosal and glans sinusoids ought to be updated. Before the penile hilum forms, the paired corpora cavernosa override the singular corpus spongiosum. The smooth muscle structure is found inside the vascular walls: the arterial, venous, and sinusoidal walls which are intertwiningly formed with smooth muscle cells and fibrous tissue structures throughout the glans penis, the single corpus spongiosum, and the paired corpora cavernosa. It is no stretch to say that the human penis mimics the structure of the human body, in which the skeletal muscles and skeleton encompass visceral organs and their containing smooth muscles. The health of the organs depends upon the integrity of its muscles, and such is the case in the structure of the penis as well.

Urethra

Another critical function of the penis is the passage of urination, which occurs via the urethra (Fig. 2). The male urethra, formed from the endodermal portion of the caudal membrane, runs through the corpus spongiosum and is composed of six parts: the bladder neck, the prostatic urethra, the membranous urethra, the bulbous urethra, the penile urethra, and the fossa navicularis. The urethra receives its blood supply from both proximal and distal directions. The bladder neck's internal sphincter is encircled by fibromuscular band covered with transitional cell epithelium. It is closed during ejaculation; a retrograde ejaculation occurs if it is otherwise dysfunctional. The prostatic urethra is the segment, 3–5 cm in size, which extends from the bladder neck to the deep perineal membrane. The verumontanum, (Latin: *colliculus seminalis*), is positioned in the middle of the prostatic urethra as well as the prostatic utricle, which is a remnant of the embryonic Müllerian duct. The ejaculatory ducts open on either side of it into the urethra. It serves as a landmark for acknowledging the external urinary sphincter just distal to it.

The membranous urethra is the shortest and narrowest part of the urethra, which measures only 1–2 cm, although it is susceptible to straddle trauma. It runs through the pelvic floor and is enclosed by the external urethral sphincter. The bulbar urethra

is widest and surrounded by the spongiosal body, and the penile urethra is the longest segment, accounting for some 15–20 cm. Cowper's gland presents in the proximal spongy urethra, whereas the urethral gland of Littre presents on the floor of the urethra and spans its entire length. Both glands are responsible for mucus secretion, which lubricates the urethra for ejaculate. The fossa navicularis represents the terminal portion of the spongy urethra, which increases in diameter just proximal to the meatus.

The wall of the urethra consists of mucosa with variable epithelium. The bladder neck and prostatic urethra contain transitional epithelium, the spongy urethra is covered with stratified columnar epithelium, and the fossa navicularis is covered with squamous epithelium, which is designed to withstand the stresses of abrasion. The submucosal layer contains connective tissue, glands, and some a very thin muscularis. The urethral lumen morphology varies throughout its length: it is crescentic in the prostatic urethra, stellate in the membranous urethra, trapezoidal in the bulb, horizontally configured along the penile urethra, and an inverted T-shape—vertically configured—in the meatus. This results in a spiral urination stream; it is hypothesized that this is advantageous for effective propulsion, and thereby the excretion of urine from the body, which has a cleansing effect on the meatus. Forking urinary streams or other urinary difficulties is a sign of urethral stricture of escalated severity.

Penile Arterial System

To meet the demands of a variably flaccid and rigid penis, the penile vascular system is unique: both the arterial supply and the venous drainage comprise a dual system which is appropriate for tissue metabolism and sinusoidal functions. The penis has a dual blood supply to the entire penile tissue and extensible sinusoids which are assorted into specific cavernosal, spongiosal, and glans entities. The superficial external pudendal branches of the femoral artery supply the tissue superficial to Buck's fascia, including the skin of the penis. These branches divide into dorsolateral and ventrolateral arteries, which provide collaterals across the midline, and contain a rich subdermal plexus. The arterial supply of the structures deeper than Buck's fascia ultimately arises from the anterior division of the internal iliac artery, which gives rise to the internal pudendal artery (Fig. 3).

The internal pudendal artery leaves the pelvis through the greater sciatic foramen below the piriformis. It travels in Alcock's canal (within the ischiorectal fossa) along the surface of the obturator internus. After it pierces the deep perineal membrane, it delivers blood to three additional penile arterial branches. The first branch is the bulbourethral artery, which runs medially in the deep perineal space to supply the corpus spongiosum and the urethra. It also anastomoses with the penile cavernosal and dorsal artery in the glans to ensure that the urethra has both an anterograde and retrograde vascular supply. The second branch is the cavernosal artery, which supplies blood to the penile crus and runs forward along the entire sinusoids of the corpora cavernosa via multiple helicine arteries and which plays a predominant role in erectile function. This is a typical example of an end artery, which is also expressed in the retina and kidney glomerulus. This end artery bears no anastomosis and is therefore susceptible to trauma.

The cavernosal arteries divide into branches after piercing fascial layers, especially the tunica albuginea in the penile hilum to supply the entire cavernosal sinusoids. They then divide into branches which enter, and are supported by, the sinusoidal wall. The dual arterial system is either forming a rich capillary network via many small arterial vessels, or forming the helicine arteries of Muller which are contracted and tortuous in the flaccid state, but dilated and straight in the erect state to erectile sinusoids. The vessels themselves give off tiny capillary structures which supply the trabecular tissue and are most abundant in the posterior aspect of the corpora cavernosa.

The paired dorsal arteries (DAs) run over the penile crus toward the midline where it pierces the suspensory ligament along with the DDV, the CV medially, and dorsal nerves laterally. This artery plays a minor role in supplying blood to the cavernosal sinusoids throughout its course along the entire corpora cavernosa (except for the penile crura). Furthermore, this artery supplies the glans penis, tissues superficial to Buck's fascia (including the Colles' fascia), the dermis, and skin.

Penile Venous System and Erection-Related Veins

There is a general rule that the ratio of number of veins to number of arteries is 2:1 in the tissues of the adult human body. A reverse 1:2 ratio exists in the fetal umbilicus and in the conventional penile venous anatomy. The venous system of the human penis has been widely studied and is generally categorized into superficial, intermediate, and deep venous systems, which are responsible for venous drainage of the superficial, intermediate, and deepest penile tissues, respectively. The superficial dorsal vein (SDV) is located between Buck's fascia and Colles' fascia for general venous drainage of superficial tissues, and a single DDV accompanied by a pair of DAs is positioned between the tunica albuginea and Buck's fascia for blood drainage of the corpora cavernosa, a chamber essential to facilitating a rigid erection. Finally, the deep vein system includes the crural and CVs for drainage of the deep tissues. Thus, according to the received medical wisdom, the penis, like the umbilical cord, constitutes a rare exception in the human anatomy in that its attendant arteries number fewer than its attendant veins do.

Recent serial studies, however, found that each of the DAs is sandwiched by a medial and lateral PAV and that the DDV is accompanied by CVs which are more deeply housed in their own perivascular sheath in accordance with the drain corresponding to the corpus cavernosum (Fig. 3). It is important to recognize that the DDV is not exclusive in having dedicated emissary and circumflex veins; the CVs and PAVs also possess them. The DDV is located in the median groove between paired corpora cavernosa and is confluent from five to seven veins with digital distribution emerging from the glans penis; it receives blood from the corpora cavernosa through emissary veins and from the corpus spongiosum through the circumflex vein. In other words, it remains the common drainage channel of the paired corpora cavernosa and the corpus spongiosum. It is flanked by a pair of CVs which are distributed along the entire length of corpora cavernosa, although these lie in a deeper position. Bilaterally, each DA is respectively

Fig. 3 Illustration of new penile vascular anatomy. (A) Lateral view: The glans penis is composed of specific sinusoids and a stout distal ligament (the *os penis* analog) for supporting the entire glans. The DDV is consistently in the median position and receives blood of the emissary veins from the corpora cavernosa and of the circumflex vein from the corpus spongiosum. The DDV is sandwiched between the cavernosal veins (CV), but these lie at a deeper position. Bilaterally, each dorsal artery is respectively sandwiched by its corresponding medial and lateral para-arterial veins (PAVs). Note that the lateral PAV merges with the medial vein proximally. The deeper color of the veins indicates the deepest part of the vasculature. The pudendal artery and nerve are distributed in a similar manner, but are relatively simple. (B) Cross section of the mid-penis: Note that the number of veins is seven (a larger count than the traditionally described singular vein), although it drops to four at the level of the penile hilum because each pair of the veins merges. Erection-related vasculature is arrayed in an imaginary arc on the dorsal aspect of the tunica albuginea, which is composed of multiple collagen bundles with a 360 degrees complete inner circular layer and a 300 degrees incomplete outer longitudinal coat. Thus, the penile vascular system still complies with the general rule in the body that the number of veins is normally higher than the number of arteries.

sandwiched by its corresponding medial and lateral PAVs. A slumped-looking communicating vein can clearly be identified between the two, acting as a kind of hammock or sling for the corresponding dorsal artery. The lateral PAV merges with the medial one proximally. Therefore, the number of veins between the tunica albuginea and Buck's fascia in the pendulous portion of the penis is seven, not one as was traditionally believed. (Although the number becomes four at the level of the penile hilum as a merger takes place in each pair of nomenclature veins.) Finally, all drainage veins account for six to eight independent channels which exit the cavernosal body and drain into the prostatic venous plexus of Santorini. Hence, the penile erection related vascular system still

Fig. 4 Cavernosogram showing erection-related veins and photo demonstrating lymphatic vessel. (A) In a 29-year-old male, an A-P view cavernosogram shows the superficial dorsal vein, circumflex veins, and cavernosal veins are directly drained to the internal pudendal vein and femoral veins (*black asterisk*) via a #19 scalp needle (*white asterisk*). (B) This photo presents a transparent lymphatic vessel (*white arrow heads*), superficial veins (tagged by a black silk suture, *dotted arrow*) above the Colles' fascia and the deep dorsal trunk (tagged by a brown chromic suture, *arrow*) which is under Buck's fascia.

complies with the general anatomical rule that veins number more than arteries do. Erection-related veins are arrayed in an imaginary arc on the dorsal aspect of the corpora cavernosa.

The blood drainage of the corpus spongiosum is required given the excessive amount of spongiosal sinusoids in each erection occurrence. Bulbo-urethral veins drain the corpus spongiosum, the urethra and the glans penis. Those veins will join the internal pudendal vein, which will drain to the internal iliac vein. Most blood in the glans sinusoids will drain to DDV, CVs, and PAVs, and some will be conducted to the corpus spongiosum.

The relationship of the vasculature to the penile fibroskeleton is interesting, and the difference between the penile venous and arterial paths is substantial. The veins traverse an oblique path between the inner and outer layers of the tunica albuginea, whereas the arteries take a more direct route. This design is optimal for facilitating penile erection in that the venous vasculature is susceptible to being compressed. In this new understanding of the penile venous anatomy, the conventional crural vein or cavernosal is just a variant circumflex vein which exits from either the lateral or medial aspect of the penile crus. This concept can be well applied to cavernosography on patients (*Fig. 4A*) whose erection-related veins are directly communicated with the superficial venous system and not apparently with so-called "deep veins." For the penile venous anatomy, a categorization of metabolic veins and erection-related veins seems to be more appropriate.

Penile Nervous System

The penis is the most sensitive organ in the male body. In the central nervous system, the medial preoptic nucleus and paraventricular nucleus of the hypothalamus and the limbic system are responsible for stimulating the spinal autonomic centers to cause erections via the action of dopamine, melanocortin, and oxytocin. The sympathetic spinal center is located in T12-L2 while the parasympathetic spinal center is located in S2,3,4. In the peripheral nervous system, the pudendal nerve arises from S2,3,4 and the pelvic plexus, which provides autonomic control.

The pudendal nerves innervate somatic motor to bulbospongiosus and ischiocavernosus muscles, as well as sensory innervations to the penis (*Fig. 3*). Afferent nerve fibers travel from sensory receptors to the penile dorsal nerve and then from the pudendal nerve into the sacral spinal cord. From here they ascend in the spinothalamic or posterior column/medial lemniscus pathway. The sympathetic adrenergic nerve fibers and receptors are present in the cavernous trabeculae, and surround the penile cavernosal arteries. Noradrenaline is the major neurotransmitter controlling penile flaccidity and de-tumescence.

The cavernous nerves arise from the inferior hypogastric plexus, located posterolateral to the seminal vesicles and lateral to the prostate gland. In the membranous portion of the urethra, the nerve fibers are located at 3 and 9 o'clock, whereas at the distal bulb of penis they are located at 1 and 11 o'clock and then enter into the corpora cavernosa. This nerve is a combination of parasympathetic and visceral afferent fibers and provides the nerve supply to the cavernosal sinusoids (*Fig. 3*). It runs dorsomedial to the penile cavernosal arteries below Buck's fascia. Accompanying arterial distribution, the cavernous nerves branch to the crus and the main trunk innervates the corpora cavernosa. The autonomic nerve fibers innervate the helicine arteries. The cholinergic nerve endings stimulate the nitrous oxide-synthase and therefore the release of nitrous oxide which is the principal neurotransmitter causing penile erection via increasing the production of cyclic guanosine monophosphate causing cavernosal smooth muscle

relaxation. In the glans penis and prepuce, the free nerve-endings are rich in quantity; there are many Meissner's and Pacinian corpuscles, which helps explain heightened sensitivity to burning, pain, temperature, position change, pressure, light touch, itch, and pleasurable sexual sensations.

Lymphatic system

The penile lymphatics initiate from the prepuce and penile skin, which run proximally toward the presymphyseal plexus via lymphatic vessels, in which some coalesce and travel at the region of the frenulum or the corona (Fig. 4B) in the company of the SDV or DDV and DA. It then diverges into right and left trunks to join the lymphatics from the scrotum and perineum. They run along superficial external pudendal vessels into the superficial inguinal nodes, especially the superomedial group. Some lymphatic drainage occurs through the femoral canal into Cloquet's node. The lymphatic vessels from the glans and penile urethra drain into deep inguinal nodes, presymphyseal nodes and, occasionally, into external iliac nodes. The lymphatics of proximal urethra drains into the pelvic lymph nodes.

Penile Fascial Layers and Ligaments

Multiple fascial layers encircling the central sinusoids comprise the structural character of the human penis (Fig. 3B). The fascial layer has a sliding ability prerequisite for erectile function and is composed of five enveloping layers: these layers, in order from innermost to outermost, are the tunica albuginea, Buck's fascia, Colles' fascia, dermis and skin. (*ABCDs* is a simple mnemonic used to describe the human penile structure.) The tunica albuginea is the coat of the corpora cavernosa, which is the deepest fascia and is composed of inner circular and outer longitudinal collagen fibers in organized arrays interlaced with elastic fibers that form an irregular, latticed network on which the collagen fibers rest. The more distal the elastic fibers, the more abundant they are, enabling the extensibility of the distal penis during an erection.

Originating from the subtunical plexus, emissary veins travel between the inner and outer layers of the tunica and usually exit the outer layer in an oblique fashion. The outer layer of the tunica is lacking between the border of the corpora cavernosa and the corpus spongiosum and acts as the determinant structure for achieving erection rigidity, which results from sealing off the venous outflow. Subsequently, the Buck's fascia encircles the corpora cavernosa and corpus spongiosum in one package. This layer is regarded as the deeper layer—*fascia penis profunda*—and pushes erection-related vasculature against the tunica albuginea; this vasculature involves the dorsal nerve, dorsal artery, DDV, CVs, PAVs, and lymphatic vessels. In addition, the Buck's fascia is endorsed with smooth muscle from the tunica dartos arising from within the scrotum. This implies that this structure is indispensable to connecting the penile shaft and scrotum. A contracted scrotum is then normally seen in a rigid erection.

Colles' fascia further solidifies the integrity of the penile structure and encompasses several SDVs, unnamed nerves, arteries, and lymphatic vessels. This layer is in continuity with the superficial perineal fascia caudally and to Scarpa's fascia of the abdomen cranially. Therefore, this sound arrangement can restrict penile hematoma formation to the area between the inguinal ligament and the fascia lata and ventral to the perineal body of the pelvic floor.

The dermis layer presents as connective tissue enveloping the inner penile tissues. This thin, loose tissue, abundant in smooth muscle layer, is continuous at the root of the penis with connective tissue in the scrotal Dartos fascia. In the penis, Dartos fascia is loosely attached to the skin and Buck's fascia below, and contains superficial vascular, nervous plexus, and lymphatic vessels. In the perineum, Dartos fascia is continuous with the superficial perineal Colles' fascia. At the penile neck, it folds back on itself to form the foreskin (prepuce) which is directly continuous with the fibroelastic shell over the glans penis. Immediately proximal to the meatus, it folds again to fuse a median raphe forming the frenulum, located on the ventral side of the glans, and attaches the prepuce to the glans, where the frenular artery is covered and extraordinarily sensitive due to its numerous nerve-endings. All tissues are covered by a skin with a stratified squamous epithelium, but the deeper urethral meatus, where a number of small, highly sensitive papillae are covered by mucosa or skin. In summary, an integral penile structure (identified by the mnemonic *ABCDs*) comprises a highly complex anatomy, even though the penis appears, at least superficially, to be a simple organ. Additionally, the prepuce presents an inner and outer leaf and covers the glans of the flaccid penis to varied extent.

At the proximal end, the entire penile structure is attached firmly to the pelvic wall via the suspensory ligament superiorly, via the fundiform ligament laterally, and (remarkably tenaciously) via a skeleton-fibrous cavernosal ligament inferiorly. The fundiform ligament, without elastic component, extends from the inferior border of the rectus sheath and linea alba; it splits into two fasciculi which encircle the root of the penis. The richly elastic suspensory ligament passes caudally from the lower end of the linea alba, forming upper fibers, and from the symphysis pubis, forming lower fibers. Together they form a strong fibrous yet elastic component, which extends to the upper surface of the root of the penis, where it blends with the Colles' fascia. This characteristic is impressive because its collagen bundle look likes an elastic lace under direct observation by microscopy.

The importance is second to none on those relevant structures to penile reconstruction. Inside the glans penis, there is a distal ligament supporting the glans penis, and the ability to engage in coitus can be ruined if a penis loses an intact distal ligament—even though its erectile function may be otherwise normal. This unique anatomical arrangement may explain why the glans penis is strong enough to bear the buckling pressure of coitus, as well as how an erect penis is sufficiently rigid but never compresses the corpus spongiosum, which otherwise would present an obstacle to ejaculation. A strong glans protects the reflexogenic erectile mechanism which may be evoked in response to global contraction of the perineal muscles, which in turn compresses the veins and the erectile tissue to encourage penile rigidity and allow a rhythmic ejaculation. Overall, an integral penile anatomical structure is a fundamental requirement for healthy erectile function and as a conduit for urinary and seminal fluids.

Clinical Relevance of Penile Structure

Congenital Abnormality of the Penile Form

Congenital defects may occur if abnormality ensues during embryonic development. Aphallia is a rare (1 in 5.5 million births) congenital condition in which developmental failure of the genital tubercle causes non-formation of the phallus: the penis, including the corporeal bodies, is completely absent. The urethra may open at any point of the perineal midline from the pubis to the anus or anterior wall of the rectum. Even rarer (1 in 30 million births) is diphallia, which is duplication of the penis resulting from an incomplete fusion of the genital tubercle, in which two distinct forms of penile duplication are recognized. The most common form is associated with bladder exstrophy complex. The patient exhibits a penis resembling that of a bird's, which consists of two separated corpora cavernosa that are associated with two separate hemiglans. Rarer still is triphallia, a condition which is similar to diphallia except that, as its name indicates, describes the occurrence of three distinct phalluses.

Diseases in the Tunica Albuginea-Related Penile Dysmorphology

There are two forms of penile dysmorphology which may be categorized as congenital and acquired entities. Penile curvature results from asymmetrical development of the tunica albuginea whereby the outer longitudinal layer is the determinant structure for penile erectile shape. This structure is the determining structure for penile morphology and penile prosthesis protection and was not identified until the 1990s. Peyronie's disease is an inflammatory condition that is characterized by the formation of fibrous, noncompliant plaques within the tunica albuginea. A hypothesized pathophysiology is repeated tunical mechanical stress and microvascular trauma as well as abnormal wound healing. The Peyronie's plaques are most likely produced by tunical fibroblasts in response to cytokine stimulation.

Diseases of Penile Vascular System

Penile veno-occlusive dysfunction (also known as penile leakage) is the leading cause of erectile dysfunction and thus has attracted a great deal of medical attention. Similarly, penile arterial insufficiency has attracted medical attention for almost a century and is potentially a sign of cardiovascular disease. Given that approximately 30% of males with erectile dysfunction are disappointed with the results of phosphodiesterase-5 inhibitor agents, the demand for—and research into—alternative treatments has steadily increased. A more lasting treatment would require the complete occlusion of the leakage points where the emissary veins are the target.

Diseases in the Prepuce

Phimosis is frequently found and smegma is easily formed in an open sac formed by the preputial inner and outer leaf. A balanoposthitis results consequently from chronic inflammation, which an infant may suffer from if the foreskin cannot be retracted in order to free the glans penis; in older males, this may aggravate a retrograde urethritis and/or contribute to a urinary infection. A circumcision is indicated once the acute infection is mitigated.

Diseases in the Male Urethra

Hypospadias is diagnosed if the urethral opening presents somewhere besides the tip of the glans penis. Surgical repair (conducted as early as possible) is recommended.

Disease in the Penile Nervous System

Any condition that jeopardizes the penile innervation will compromise the integrity of penile health either centrally or peripherally, which will, in turn, result in erectile dysfunction because erectile tissues are unable to fill with blood. These include prostatectomy nerve injury, traumatic nerve injury, etc.

Disease in the Lymphatic System

Lymphedema is a condition of lymphatic blockage resulting from external or endogenic causes including infection; some foreign bodies are not uncommon to encounter such as paraffin, glass ball and hyaluronic acid, etc.

Glossary

Detumescence The inverse of tumescence, detumescence describes a state of the penile corpora cavernosa in which blood from erection-related veins drains back into the larger circulatory system.

Ejaculation An action of gushing fluid composed of semen and sperm, initiated by peristalsis from the semiferous tubule along the epididymis, seminal vesicle, ejaculation orifice, prostate urethra, external sphincter, membranous urethra and penile urethra to the urethral meatus.

Erection rigidity Refers to varying grades of erectile rigidity, with peak rigidity (a full erection) characterized by a bone-like hardness in the penis.

Intracavernosal pillars Fibroelastic tissues distributed between the 10 or 2 o'clock to 6 o'clock positions of the inner tunical layer of the corpora cavernosa. The pillars are intertwined with collagen bundles and elastic fibers.

Nitric oxide activities A key neurotransmitter to relax smooth muscle of the vascular endothelium within the sinusoidal wall of the paired corpora cavernosa, the lone corpus spongiosum, and the glans penis.

Parasympathetic activity The part of the autonomic nervous system that is responsible for regulating the penile sinusoids into tumescence, which results from increased penile arterial supply and decreased venous outflow when active; in the autonomic nervous system, it is the counterpart to sympathetic activity.

Penile arterial inflow An extent of penile artery supply to the sinusoids of the penis, it is largely routed to the corpora cavernosa where arterial supply speed varies from 2–3 mL/min to 60–80 mL/min.

Penile cavernosal-sinusoidal trapping A state of the penile sinusoids in which the penile arterial supply exceeds venous drainage, resulting in sinusoidal expansion.

Smooth muscles One of the muscle categories, the *smooth* muscles scatter along the vascular wall, gastrointestinal tract, reproduction tract, sinusoidal walls, etc.

Sympathetic tone The part of the autonomic nervous system that is responsible for regulating the penile sinusoids into detumescence resulting from increased venous outflow and decreased penile arterial supply; in the autonomic nervous system, it is the counterpart to parasympathetic activity.

Tunica outer longitudinal layer A tenacious collagen layer surrounding the corpora cavernosa, the collagen fibers in organized arrays interlaced with elastic fibers that form an irregular, latticed network on which the collagen fibers rest. This tissue determines drainage speed and the penile morphology and is the pivotal coat to protect an implanted prosthesis.

Tumescence Inverse of detumescence, tumescence describes a state of the penile corpora cavernosa characterized by sinusoidal expansion resulting from increased penile arterial supply and decreased venous drainage of erection-related veins.

Venous drainage A term that describes the return of sinusoidal blood back to the larger systemic circulatory system following an erection.

The Human Penile Structure and Erections

Comparative Anatomy in Mammals

In male animals, the os penis (the penis bone) exists in most species to achieve the best chance of paternity; this durable structure increases the coital frequency and often the duration as well. The penis bone, which is attached to the tip of the penis rather than the base, provides structural support for male animals that engage in prolonged intromission. The longest sexual intercourse was performed by a couple of rattlesnakes (*Crotalus L.*) that made love for 23 h and 15 min (Fig. 1). The coital duration is not proportionally correlated, though: for instance, while a male lion's os penis allows him to engage in an impressive 250 copulations in 4 days, each copulation can only last for a minute (which is still longer than that of a male rat, for whom copulation lasts only a few tenths of second). However, the male's hardy os penis makes it easy to get geared up for the next willing female shortly after his previous ejaculation. Although mounting is always required in mating behaviors, a male dog can swing its penis in a right-about direction after successful mating. This facility is particularly impressive, since there is neither a truly synovial joint nor a synarthrosis inside the canine penis. The answer might lie in the peculiar anatomy of the canine penis, which is composed of a long os penis in the front and a stout and minimally expandable corpora cavernosa at the rear.

Humans, woolly monkeys, and spider monkeys are the only primates lacking this hardy piece of anatomy. How do human males manage to function (sexually) without an os penis if, as conventional wisdom suggests, no os analog structure exists? It is a good question, but the human penis may have no need for an os penis given that erection rigidity is attained through a hydraulic

Fig. 1 Comparison of penile structure in different species, cross-sections of the corpora cavernosa and longitudinal aspect of the glans penis are from A to C and D to F, respectively. (A) In rats, the corpus cavernosum, devoid of the medial septum and intra-cavernosal pillars, is positioned between the deep dorsal vein (*arrow*) and the urethra (*arrowhead*) (H & E stain, reduced from 25 $\times$). (B) In dogs, a complete septum (*arrow*) and abundant intracavernosal pillars are obvious (1 $\times$). (C) In male humans, an intracavernosal pillar is not uncommonly encountered (not demonstrated). A septum (*arrow*) is significant, but incomplete and dorsally fenestrated. Note the clear delineation of the inner circular and outer longitudinal layers of the tunica albuginea (1 $\times$). (D) In rats, a short os penis is positioned between the glans penis and the corpus cavernosum (left panel, 7 $\times$). The amount of glanular tissue is scanty. The junction between the glans penis and the corpus cavernosum looks like a knee joint, which provides a flipping action during mating. The short os penis (right panel, 1 $\times$) can be better demonstrated after clearing and alizarin red S staining because only bony tissue can be preserved. (E) In dogs, the os penis (*double-headed arrow*) is enveloped with a unique glans penis of two compartments (*arrowhead* and *arrow*, respectively). Similar to the rat penis, the corpora cavernosa are not intromitted. However, they are reinforced with abundant intracavernosal pillars and a complete septum (1 $\times$). (F) In male humans, the distal ligament (*arrow*) within the glans penis is obvious and should be regarded as a ligamentous structure rather than a mere collection of sinusoids. The distal ligament is an aggregation of the outer longitudinal layer of the tunica albuginea and acts as a buttress of the glans penis (1 $\times$). Courtesy reproduction from *Journal of Andrology*, 26(5):624–628, 2005.

system rather than a bony structure. To know the relation of structure and peculiar function in the human penis, it is advisable to first know the comparative penile anatomy in varied species.

Recently a study was done on rat, dog, and human penises. In the rat's penis, although there is a short os penis, performing a flipping action with a rigid erection would be challenging, as neither a significant septum nor intracavernosal pillars is found in the corpus cavernosum (**Fig. 1A**). In dogs, with their long os penis, there is a complete septum between the paired corpora cavernosa as well as abundant intracavernosal pillars located behind the os penis (**Fig. 1B**). In human beings, for extraordinary hydraulic extensibility there is an incomplete septum with dorsal fenestration and moderately abundant intracavernosal pillars in the corpora cavernosa (**Fig. 1C**), which allows free communication between the two corpora cavernosa.

The anatomical structure of the glans penis varies between different species. In the glans penis of both rats (**Fig. 1D**) and dogs (**Fig. 1E**), there is a bony structure, i.e., the os penis. In these mammals, the os penis is the only supporting structure in the glans penis; there is no synovial joint in the species. In contrast to these os penises, the human glans penis contains an os analog, named the distal ligament (**Fig. 1F**). This newfound structure is inelastic and formed through an aggregation of the outer longitudinal layer of the tunica albuginea, in which neither a vascular component nor nerve tissue is seen. Moreover, many tributaries of supporting structures radiate directly from the distal ligament.

In histological sections, the os penis is composed mainly of type I collagens interlocked with type III collagens both in rats (**Fig. 2A**) and dogs (**Fig. 2B**) while connecting the os penis with its fibrous envelope. In humans, the distal ligament is composed of type I collagens (**Fig. 2C**), and neither osteocytes nor chondrocytes, characteristics of the bony structure, are found. The distribution of intracavernosal pillars is intermediate between the rat and dog; its pronounced wavy appearance results from

Fig. 2 Histology of the os penis, os analog, and intracavernosal pillars of the human penis. (A) In rats, the type I collagen with a reddish appearance is the major component of the os penis, which can be regarded as a woven bone (upper). The interlocking type III collagen with a greenish appearance is uncommon in the os penis proper, but substantial in its envelope (lower) (Picrosirius red stain, 400 $\times$). (B) In dogs, the appearance of a lacuna is characteristic. Osteocytes as well as chondrocytes are seen (Picrosirius red, 100 $\times$). (C) The os analog of human beings is similar to the os penis of a dog. Type I collagen is also the major component, with type III collagen as an interlocking ingredient. However, there are neither osteocytes nor chondrocytes (Picrosirius red, 400 $\times$). (D) In the human penis, the distribution of intracavernosal pillars is intermediate between the rat and dog (**Fig. 1B**); its pronounced wavy appearance results from an extraordinary extensibility via elastic component (Picrosirius red, 25 $\times$). Courtesy reproduction from *Journal of Andrology*, 26(5):624–628, 2005.

extraordinary extensibility via the elastic component (**Fig. 2D**). Moreover, in the tunica albuginea of the corpora cavernosa, elastic fibers are sparse in the canine penis, few in the murine penis, and abundant in the human penis.

During mating, only the long os penis, associated with its glans penis, is intromitted, but the corpora cavernosa are not because these are deeply buried in the male body and can only act as a support of the long os penis. Therefore, either the junction between the os penis and the corpora cavernosa or that of the os penis to the glans penis is extraordinarily strong.

In dogs, the overwhelmingly abundant intracavernosal pillars and a complete septum will enhance the strength of the corpora cavernosa. In rats, the mounting duration is so short that these enhancing micro-architectures are not necessary. The resulting insufficient rigidity may, in turn, facilitate the flipping movement of the intromitted penis for the removal the semen plug deposited by a previous male. In human beings, the corpora cavernosa are intromitted. The intracavernosal pillars and the septum may increase dispensability and may, therefore, be mandatory in order to establish sufficient rigidity by congestion of the sinusoids if longer coital time is required. This suggests that a man may be susceptible to premature ejaculation if his penis is erect but insufficiently rigid. A complete septum meets the requirement for establishing a pair of sufficiently strong corpora to buttress a long os penis such as that found in dogs, and the absence of this structure will be sufficient to support a short os penis whose mounting time is as short as a few of tenths second, as it is in rats. In human beings, the medium septum with its unique dorsal fenestration is observed, and the paired corpora cavernosa may be regarded as an ideal milieu to apply Pascals' law which states that pressure applied to any part of the enclosed fluid at rest is transmitted undiminished to every portion of the fluid and to the walls of the containing vessel. It appears to be enforced with intracavernosal pillars; sufficient erectile rigidity could not otherwise be reached. Not surprisingly, therefore, one donor artery is sufficient in attempting arterial reconstruction. Plenty of elastic components in the tunica albuginea of the corpora cavernosa thus increase the erectile capability of the penis. Overall, this implies that not only the increment of erectile length, but also the erectile girth of the human structure may, therefore, expand.

Essential Structures for Erection Rigidity in the Human Penis

Human males lack an os penis but instead possess an os analog—the distal ligament—located within the glans penis. It is complemented by the human penis's evolved hydraulic system. However, this particular evolution is not without its disadvantages because a hydraulic system is vulnerable to insufficient rigidity if veno-occlusive dysfunction exists. Unsurprisingly, it is common for physicians to encounter males who suffer from erectile dysfunction, which is defined as difficulty (or inability) to attain or maintain an erection of sufficient rigidity. It is also not uncommon for young boys to question their parents and ask why the penis is

Fig. 3 An illustration of the relationship between sinusoids and emissary veins in human corpora cavernosa. Left: A cross-section of the human corpora cavernosa. Right: An amplified view of an emissary vein and its supplying sinusoids. Their anatomical relation is like a cluster of grapes, where the emissary veins are regarded as the grape stems and each sinusoid as the fruit.

sometimes soft like a worm and sometimes hard like a bone. Although a functional brain is a prerequisite for healthy penile sexual function, a rigid erection can be a purely mechanical event arising within penis itself—some males can sustain a full, rigid erection resulting from reflexogenic activity (originating between the 2nd and 4th vertebrae of the sacral spine) despite sustaining an injury to the upper spinal cord.

It is necessary to describe the indispensable structures for achieving erectile rigidity. There are six essential structures to reach this aim: healthy sinusoids, a functional tunica albuginea (especially the outer longitudinal layer), intact intracavernosal pillars, an integral distal ligament, and normal ischiocavernosus and bulbospongiosus muscles. The seamless interplay of the tunica albuginea and cavernosal sinusoids is the primary step of a penile erection (Fig. 3). The cavernous artery delivers blood to two types of branches: firstly, to the outer capillaries, which are responsible for supplying nutrition to the penis in the flaccid state as well as the smooth muscle and nerve fibers; secondly, to the inner helicine arteries (Fig. 1, left), which open directly into cavernous spaces without entering capillaries, which are then emptied into the post-cavernous venules. These inner arteries are for fulfilling the erectile function; they are shaped like corkscrews and allow the penis to elongate and expand without compromising flow. Multiple layers of smooth muscle surround the helicine branches. This muscle is contracted while flaccid, allowing only small amounts of blood into the lacunar spaces. After the appropriate stimulus, muscle relaxation occurs and the arteries dilate and straighten, increasing blood flow and dilating the lacunar spaces and, in turn, applying pressure against the outer longitudinal layer of the tunica albuginea to reduce the blood drainage, which eventually results in a rigid erection. Application of real world physics would assume that the corpora cavernosa comprise an ideal vessel in which to apply Pascal's law, which states that pressure applied to any part of an enclosed fluid at rest is transmitted undiminished to all walls of the containing vessel. The cavernosal sinusoidal expansion and decreased venous drainage result from tunical synchronizing limitation. The tunica albuginea is a bi-layered structure with a 360° inner circular and a 300° outer longitudinal layer which is the buttress against the sinusoidal wall to seal off the emissary veins which pass obliquely along the inner and outer longitudinal layer, an extension from the ischiocavernosus and bulbospongiosus muscles. The 360° inner layer encircles a cavernosal membrane to completely contain the erectile sinusoids and—together with the intra-cavernosal pillars—supports the cavernosal sinusoids. The distal ligament is an os penis analog and is arranged centrally and acts as a trunk of the glans penis to maintain patency of the distal urethra and preserve the range of ejaculation; it helps maintain the integrity of the entire penile structure while an intracavernosal pressure surge is conveyed distally. These structures, and their respective functions, are all indispensable for achieving penile erection and physiology.

Important Neuronal Center and Neurotransmitter for Erection

It is difficult, if not impossible, to enjoy a love life without a healthy working central nervous system. This is especially true for sexual activity because erection, emission, ejaculation, and orgasm are specifically coordinated by corresponding areas in the brain. The medial preoptic nucleus, paraventricular nucleus of the hypothalamus, and the limbic system, via the action of oxytocin, melanocortin and dopamine, are responsible for stimulating the spinal autonomic centers to cause erections. The sympathetic spinal center is located in the 12th thoracic vertebra to the 2nd lumbar vertebra and the parasympathetic spinal center is located in the 2nd to 4th vertebrae of the sacral spine. The baseline sympathetic tone originates from the intermediolateral gray matter of the thoracolumbar spinal cord in the 1st thoracic vertebra to 2nd lumbar vertebra. As a rule, a functional penis requires

a functional heart. Penile sympathetic stimulation flows through several pathways, including the sympathetic chain ganglia (in the 1st thoracic vertebra) which also supply such structures as the heart and vascular system via the splanchnic nerve in the 5th thoracic vertebra to the 12th lumbar vertebra. The autonomic nerve fibers innervate the helicine arteries. The cholinergic nerve endings stimulate the nitrous oxide-synthase (NOS) and therefore the release of nitrous oxide (NO), which is the principal neurotransmitter causing penile erection.

Adrenergic nerve fibers and receptors are present in the cavernous trabeculae and surround the deep penile arteries. Sympathetic contraction is thought to be mediated by activation of postsynaptic alpha-adrenergic receptors and modulated by presynaptic alpha-adrenergic receptors. Noradrenaline is the major neurotransmitter controlling penile flaccidity and tumescence. Acetylcholine is required for vascular smooth muscle relaxation, and cholinergic nerves have been demonstrated within the cavernosal smooth muscle and surrounding penile arteries.

Non-noradrenergic, non-cholinergic (NANC) neurons release NO, which in turn increases the production of cyclic guanosine monophosphate (cGMP), a second messenger, causing cavernosal smooth muscle relaxation. Other neurotransmitters, including vasoactive intestinal peptide (VIP), calcitonin gene-related peptide (CGRP), prostaglandins, and other peptides, are also thought to be involved in the erectile process. Therefore, it is understandable that both sexual stimulation such as sexual thoughts (psychogenic stimuli) and genital touch (reflexogenic stimuli) can produce a penile erection.

Human Erection Mechanism

Erection Physiology

The human erection results from a complex interplay of psychological, hormonal, neurologic, vascular, and cavernosal contributors with a neuronal and endothelial nitric oxide effect. A firm erection requires good arterial blood inflow, trapping of sinusoidal blood, and limiting venous outflow of erection-related veins. It is commonly agreed to use six phases for describing an erection cycle. In order to provide a comprehensive overlook, the Table 1 Summary details the entire erection process. The autonomic nervous system controls penile state, which varies between flaccid and erectile states; two system sub-branches, the sympathetic and parasympathetic, are located in the 12th thoracic to 2nd lumbar vertebra and in the 2nd to 4th sacral spine, respectively. The higher center for the autonomic system is in the thalamus, and, unsurprisingly, the sympathetic and parasympathetic systems are also appointed to the thoracolumbar and craniosacral systems. The penis is usually kept in a spongy-soft flaccid state (Fig. 4) by a baseline sympathetic tone, which precipitates release of norepinephrine from penile adrenergic nerves, resulting in tonic contraction of the smooth muscle cells of the sinusoidal trabecula and penile arterioles as well. The human penis itself is a hydraulic system which depends on the vascular system; thereafter, this smooth muscle contraction results in significant resistance to arterial blood inflow and prevents cavernosal sinusoids from expanding, thereby keeping the penis in the flaccid state (flaccid phase). Not surprisingly, norepinephrine is released when a man experiences pain or stress, which in turn fades an erection even if the penis is in a fully erect state. Norepinephrine also likely inhibits the release of nitric oxide, thereby further inhibiting stimulation of erections; consequently, the male penis is kept in a flaccid state. Its counterpart parasympathetic system plays a role in re-starting the erection process.

Whenever sexual arousal ensues—originating either from the brain or from peripheral stimulation (latent phase)—there is a rapid impulse increasing parasympathetic activity which overrides the basal sympathetic tone. Increased parasympathetic tones result in a decrease in norepinephrine levels and an increase in acetylcholine release, which in turn increases nitric oxide synthase activity; subsequently, nitric oxide releases from both non-adrenergic, noncholinergic neurons and endothelial cells of vascular tissue and cavernosa sinusoids. Then, nitric oxide enhances, or inhibits the degradation, of both intracellular second messengers—cGMP (cyclic guanosine monophosphate) and cAMP (cyclic adenosine monophosphate). A profound smooth muscle relaxation (especially in the cavernosal sinusoids of the corpora cavernosa) results in encouraging helicine artery supply, increasing sinusoidal expansion, and limiting venous drainage outflow of erection-related veins. It is well-elucidated that increasing nitric oxide neurotransmitters stimulates adenylate cyclase to elevate intracellular levels of cGMP. Both cGMP and cAMP are potassium channel openers that lead to hyperpolarization within the cells and, subsequently, cause closure of voltage-dependent calcium

Table 1 Summary of six phases for the erection process

Phases
Flaccid: Resting state with minimal arterial inflow at around 2–3 mL/min, which is good for physiological purposes
Latent: Sexual stimulation, either central or local, causes increase in arterial inflow which could elevate to 60–80 mL/min
Tumescence: Rapid elongation and girth expansion of penis resulting from sinusoidal expansion to limit the outflow of erection-related veins ^a
Full erection: Complete penile expansion characterized by high intra-corporeal pressure and decreased arterial inflow
Rigid erection: Ischiocavernosus and bulbospongiosus muscle contraction with further surge in intracavernosal pressure
Detumescence: Increased venous outflow and decreased arterial inflow until a flaccid state is resumed

^aPenile erection-related veins (PERV) include one deep dorsal vein, two cavernosal veins, and two pairs of para-arterial veins.

Fig. 4 A schematic illustration of the human erection process in six-phase cycle. Bottom: Lateral aspect. The penis leans upon the suspensory ligament, which is an extension of the linea alba. It is capped by the glans penis. Proximally, the corpus spongiosum is held by the bulbospongiosus muscle, in which the fibers are mostly transverse. The corpora cavernosa are surrounded by the tunica albuginea, which is a bi-layered structure consisting of an inner circular and an outer longitudinal layer with multiple sublayers. The intracavernosal pillars, which may be considerably larger distally, are a continuation of the inner circular layer. The corpus cavernosum is entrapped in the ischiocavernosus muscle, with the muscle fibers aligned in the longitudinal direction. Note the distal ligament within the glans penis. In the middle, a cross-section of the corpora cavernosa depicts the anatomy of the penile shaft. Uppermost: Pictures I–VI depict, step by step, that the penile helicine artery and cavernosal sinusoids dilate, thereby blocking the emissary veins; also depicted is the cavernosal sinusoids' response when a central sexual arousal ensues. The erection process is divided into six phases: flaccid, tumescence, latent, full, rigid, and detumescence, with the final step leading back to a flaccid state.

channels, which, along with intracellular organelle sequestration of calcium, leads to decreased intracellular calcium levels. An intracellular calcium drop causes the corporal smooth muscle relaxation, which enhances active dilation of the penile arteries, arterioles, and sinusoids, resulting in increased arterial inflow and sinusoidal expansion and in limited penile venous outflow of the erection-related veins. This ultimately leads to elevated intracavernosal pressure against the outer tunical layer of the corpora cavernosa.

Fulfilling effective erectile function requires a delicately synchronized cavernosal smooth muscle action, which is made possible by the presence of gap junctions located in the membranes of adjacent muscle cells. It is very likely that this synchronized erectile activity plays a pivotal role in the erection process because cavernosal smooth muscle tissue is only sparsely innervated by nervous tissue. These gap junctions allow the free exchange of a second-messenger molecules and larger ions such as calcium, which is indispensable for coordinated smooth muscle erectile activity. Active dilation of the cavernous and helicine arteries of the penis is the first event to occur during erection. This is closely followed by trabecular smooth muscle relaxation, which increases the compliance of the sinusoids, causing them to expand to accommodate the increased blood inflow. This expansion causes compression of the sub-tunical venous plexuses and emissary veins between the compliant venous sinusoids and the surrounding

noncompliant tunica albuginea—particularly the outer longitudinal layer—thereby reducing venous outflow from the penis (tumescence phase). The rapid increases in penile arterial inflow results in pressure elevation within the penis that is comparable to systemic arterial levels. These arterial inflows include the bulbourethral artery, the cavernosal artery, and the dorsal artery to supply the sinusoids in the corpus spongiosum, corpora cavernosa, and glans penis, respectively or jointly. An intracavernosal pressures exceeding 90 mmHg can be regarded as the starting point of erection, and then further rapid elevation in pressure will cause a full penile erection (Full erection phase); in particular, provided that the patient does not suffer from venous leakage, further contraction of the ischiocavernosus and bulbospongiosus muscles raises the pressure several hundred millimeters mercury just within the corpora cavernosa (rigid erection phase). However, the sinusoidal pressure of the corpus spongiosum and glans penis sustains much lower intra-sinusoidal pressure due to the virtual absence of outer tunical layer and intracavernosal pillars. This pressure difference between these anatomical structures guarantees a smooth ejaculation and also provides a “cushion” protection for a sexual partner.

Ejaculation is facilitated by rhythmic contractions of the bulbocavernosus muscles, which contribute into the ventral thickening of the tunica albuginea, positioned at around the 5 and 7 o'clock positions. An intracavernosal pressure surge can be detected because of this anatomical relationship. Ejaculation is a typical sympathetic tone climax which results in noradrenaline secretion surge, which in turn, causes smooth muscle contraction and of course detumescence, ultimately returning the penis back to a flaccid state (detumescence phase). The reciprocating cycle of penile erections described in the preceding paragraphs is perpetual unless and until a male suffers from erectile dysfunction.

Tunica Outer Longitudinal Layer Is a Key Structure for the Erection Mechanism

Although the human penile anatomy and erection physiology have been extensively studied, we may still not thoroughly understand this unique organ. In the last few decades we have endeavored to shed light on the penile tunical and venous anatomy with the discovery of a bi-layered tunica and an intriguing model of penile erection-related veins. The former substantiates a model of the tunica albuginea of the corpora cavernosa as a bi-layered structure with a 360° complete circular layer (smooth muscle component) and a 300° incomplete outer longitudinal coat (skeletal muscle component) in contrast to a single inner circular layer. (This anatomical discovery raises additional questions: How can the erection process be fulfilled if no outer longitudinal layer exists? How can emissary veins be sealed off when passing the tunica if there is just one single tunical layer?) The latter proves that one deep dorsal vein, two cavernosal veins, and two pairs of para-arterial veins (as opposed to one single deep dorsal vein) are situated between Buck's fascia and the tunica albuginea for corpora cavernosa drainage. Thus, the corpora cavernosa communicates with the larger circulatory system via the penile arterial and venous vasculature.

During the Second World War, a critically injured soldier exhibited a rigid postmortem erection following the administration of an intracavernous blood transfusion at 25 mL/min. This incident implies that the human erection could prove to be, at its core, a mechanical matter. While it is generally accepted that the human erectile mechanism involves an intricate interplay among hormonal, vascular, neurological, sinusoidal, pharmacological, and psychological factors, the mechanism itself and the relative contribution of each respective component remain somewhat unclear, and merit further study. To identify a research model for differentiating venogenic factors from psychogenic factors in the ED contributor list, cadavers were deliberately chosen. A dynamic cavernosometry was performed in 48 cadavers for various hemodynamic studies (Table 2). Between 2002 and 2003, five fresh cadavers were obtained for demonstrating the pivotal role of the penile erection-related veins in a penile erection. That study was criticized for using normal saline with a speed of 150 mL/min, which far exceeds the arterial inflow rate of 60–80 mL/Min in human penile physiology. A second criticism questioned whether and how we could prove that the sinusoidal cells were totally dead. Although normal saline is used for volume expansion in medical purposes, the viscosity coefficient is zero, and, consequently, the infusion rate will be abnormally high. We therefore use 10% colloid and defrosted cadavers to address the two concerns. We investigated the role of venous outflow to isolate the key determinant of erectile function. The dynamic infusion cavernosometry and cavernosography were conducted on 15 defrosted human cadavers, both before and after the meticulous removal and ligation of penile veins. Preoperatively, an infusion rate of more than 28.1 mL/min (14.0–85.0 mL/min) was required to induce a rigid erection. Following surgery, we obtained the same result at a rate of 7.3 mL/min (3.1–13.5 mL/min) across the entire sample. The rigid erection is a mechanical phenomenon contingent on venous competence, and penile veins are the principal component

Table 2 Summary of hemodynamic study on 48 valid human male cadavers in varied purposes from 2002 to 2013

Grouping	Cadaver		Infusion rate or volume			Purpose of study for penile erection-related veins ^b
	No.	Study time	Fluid	Preoperative ^a	Postoperative	
Fresh	5	2002–2003	Normal saline	1050 mL	89 mL	The pivotal role in erection
Defrosted	15	2009–2010	10% colloid	28.1 mL/min	7.3 mL/min	The principal component in erectile rigidity
Defrosted	7	2010–2012	10% colloid	30.2 mL/min	2.8 mL/min	Venous drainage of the corpora cavernosa
Defrosted	11	2011–2013	10% colloid			Role in penile veno-occlusive Mechanism
Total	48					

^aThe PERV stripping surgery.

^bPenile erection-related veins (PERV) include one deep dorsal vein, two cavernosal veins, and two and pairs of para-arterial veins.

for erectile rigidity. Similarly, seven cadavers were studied for exploring the venous drainage of the corpora cavernosa. Eventually, 11 valid defrosted cadavers were studied via electrocautery ($n = 6$) or ligation ($n = 5$); after exposing the defrosted cadaveric penises to electrocautery with varied intracavernous pressure, we were able to prove (indirectly) that the outer tunica acts as the determinant structure of the veno-occlusive mechanism.

Clinical Relevance of Penile Erection

Diseases of the Penile Vascular System

There are penile arterial insufficiency and penile venous occlusive dysfunction in this disease entity. The failure to attain and/or maintain a rigid erection is a common symptom of penile arterial insufficiency or veno-occlusive dysfunction. Poor penile arterial function is commonly regarded as a major cause of vasculogenic erectile dysfunction; however, penile veno-occlusive dysfunction may be the far more prevalent one. The former is frequently regarded as an early sign of cardiovascular disease. Either arterial reconstruction or endovascular treatment are feasible options. Generally, any measure that benefits cardiovascular health will potentially improve penile arterial function. The prevalence of penile veno-occlusive dysfunction may be more widespread than commonly believed. Most impotent males suffer from this problem; one set of treatment options is characterized by venous intervention. Penile venous stripping is superior among these options, which also includes conventional venous ligation, venous coil embolization, and venous sclerotherapy.

Diseases of the Penile Cavernosal Sinusoids

The corpora cavernosa comprise the most ideal milieu in the human body in which to apply the Pascal's law. It is therefore the structure that is most vulnerable to malfunction resulting from penile arterial insufficiency, cavernosal fibrosis, and excessive venous drainage. The cavernosal fibrosis may be the most ill-defined disease despite extensive research. In the natural physiology, penile cavernosal sinusoids are not vulnerable to the aging process because the sinusoidal walls are at rest most the time, which distinguishes them from other end artery organs such as the retina (which typically rests only at night) and the kidney (which works 24 h/day). Penile implants remain the gold standard if cavernosal fibrosis is so severe that all other medical treatments fail.

Diseases of the Penile Spongiosal Sinusoids

The corpus spongiosum is the structure for guarding the passage of urine and ejaculate. A tethered penile ventral deviation happens when a fibrosis of the corpus spongiosum is severe enough to constrain the elongation ability; such a deviation also potentially constrains the passage of ejaculate.

Diseases of the Glans Sinusoid

The glans penis should not be completely rigid when the penis is erect; such rigidity would diminish the "cushion" effect between the penile shaft and the vaginal wall and thereby, as well, the patency of urethral ejaculation. However, some patients present concerns about an excessively soft glans, and questions regarding this matter are frequently asked in clinical setting. The character of the glans sinusoids is specific and divergent from that of the sinusoids in the corpora cavernosa and corpus spongiosum, respectively. Excessive venous drainage should be ascribed if a patient complains his glans is too supple, although a psychogenic origin cannot be overlooked.

Diseases of the Tunical Albuginea

The erectile morphology is determined by the tunica albuginea, which is the major component of the penile fibroskeletal system. Penile dysmorphology may be due to congenital penile curvature and acquired Peyronie's disease. In addition, a severe ventral curvature is not uncommonly presented because a tethering force is generated from a fibrotic corpus spongiosum, e.g., one affected by urethral manipulation syndrome, which is a term that describes urethral fibrosis caused by insertion of a catheter or other endoscopic instrument. In the most severe cases, surgical intervention is still the best viable option.

Diseases of the Distal Ligament

Although the distal ligament—an os analog in the human penis—is a relatively newfound structure, it is deemed an indispensable structure of penile integrity. This structure is so paramount that a traumatic disruption, although rare, causes the inability to engage in penile coitus despite otherwise intact erectile function of the corpora cavernosa. A surgical repair is required if traumatic disruption occurs.

Priapism

Priapism describes a situation in which the human penis remains in a rigid erectile state for over 6 h despite the absence of sexual stimulation. It is not uncommon to encounter in a clinical setting. It is commonly categorized into ischemic, non-ischemic, and recurrent ischemic types. The most prevalent is ischemic priapism, and it occurs when blood does not adequately drain from the corpora cavernosa; it is generally painful, resulting in a corporeal rigidity but a pale and non-engorged glans penis. On the contrary,

in non-ischemic priapism—as the name suggests—the penile erection veins are not completely blocked. Non-ischemic priapism typically results from a shunt formed between the corpus spongiosum and an artery or disruption of the nerve of the parasympathetic nervous system, which enhances penile arterial inflow.

Medical history and physical examination is the first impression of the priapism which is further documented by sonography and cavernosal blood gas analysis. The most common cause of ischemic priapism is sickle cell disease followed by medication such as selective serotonin re-uptake inhibitors (SSRIs), cocaine, cannabis, and intracavernous injection agents such as papaverine or prostaglandin. Treatment strategy aims on terminating the underlying cause. In treating patients with ischemic priapism, it is typically advised to administer a nerve block (for pain relief) followed by aspiration of blood from the corpus cavernosum. A cavernosal measurement is advised by cold normal saline irrigation or, if that has no effect, then a phenylephrine injection. Non-ischemic priapism is often treated with cold packs and compression. Shunting surgery may be required if standard measures are not effective. Sequelae include erectile dysfunction and penile deviation.

Glossary

ACTH (adrenocorticotrophic hormone) Also known as corticotropin, is a polypeptide tropic hormone produced and secreted by the anterior pituitary gland.

Adrenarche It is a term to describe an early stage of sexual maturation in many higher primates that in human occurs at some 10–11 years of age. In boys, the principal physical consequences of adrenarche are especially pubic hair growth, change of sweat composition that produces adult body odor, increasing oiliness of the skin and hair and mild acne may occur.

Aldosterone The main mineralocorticoid hormone is a steroid hormone produced by the zona glomerulosa of the adrenal cortex in the adrenal gland.

Androgen A category of natural or synthetic compounds, mostly steroid hormones that stimulate or control the development and maintenance of male characteristics.

Androgen receptors It is a type of receptor in the nucleus of a cell, which is activated by binding androgenic hormones such as testosterone and dihydrotestosterone in the cytoplasm and then conveyed into the nucleus. It plays mainly as a DNA-binding transcription factor that regulates gene expression.

CAH (congenital adrenal hyperplasia) Any of several autosomal recessive diseases resulting from mutations of genes for enzymes mediating the biochemical steps of production of mineralocorticoids, glucocorticoids or sex steroids from cholesterol by the adrenal glands (steroidogenesis).

DHEA (dehydroepiandrosterone) The primary precursor of natural androgens and estrogens. It is also named as dehydroisoandrosterone or dehydroandrosterone.

DHT (dihydrotestosterone) A metabolite of testosterone, and a more potent androgen than testosterone in terms of affinity toward androgen receptors.

Erectile dysfunction The inability to either attain or maintain a rigid erection for satisfactory coitus.

GH (growth hormone) It is also known as somatotropin, a peptide hormone that stimulates growth, cell reproduction, and cell regeneration in humans and other animals.

IGF-1 (insulin-like growth factor 1) A hormone similar in molecular structure to insulin. It plays an important role in childhood growth and continues to have anabolic effects in adults.

Pubarche It is a term to describe the first appearance of pubic hair in a child. It usually results from rising levels of androgens from the testes or adrenal glands and is one of the prominent physical changes of puberty.

SHBG (sex hormone-binding globulin) or sex steroid binding globulin (SSBG) A glycoprotein that binds to the two sex hormones: androgen and estrogen.

SRY (sex-determining region Y protein) A DNA-binding protein (also known as gene-regulatory protein/transcription factor) encoded by the SRY gene that is responsible for the initiation of male sex determination in humans.

Testosterone The primary male sex hormone, an anabolic steroid, which plays the key role in the development of male reproductive tissues such as prostate, testicles and promoting secondary sexual characteristics such as hair growth and increasing muscle and bone mass.

Introduction to Androgens and Other Hormones That Affect the Penis

Androgens refer to a number of natural or synthetic compounds, mostly steroid hormones that stimulate or control the development and maintenance of male characteristics in vertebrates. They exert their action through binding to and activation of the androgen receptor which is a ligand-dependent nuclear transcription factor and a member of the steroid hormone nuclear receptor family. Given its widespread scattering in many tissues and specific cells, the androgen receptor has a diverse range of biological actions including pivotal roles in the development and maintenance of the cardiovascular, immune, neural, musculoskeletal, hemopoietic and reproductive systems.

Dehydroepiandrosterone (DHEA) is synthesized from cholesterol (**Fig. 1**). Although it functions as an endogenous precursor to more potent androgens such as testosterone and dihydrotestosterone (DHT), DHEA has been found to possess some degree of androgenic activity in its own right, acting as a low affinity ($K_i = 1 \mu\text{M}$), weak partial agonist of the androgen receptor. DHEA and DHEA-S, its sulfate metabolite, also act as a neurosteroid and neurotrophin. Although a relatively weak androgen, DHEA is responsible for the androgenic effects of adrenarche, such as early pubic and axillary hair growth, adult-type body odor, increased

Fig. 1 Illustrative algorithms in human androgen production. Endogenous production of androgens and estrogens from the cholesterol which is the precursor. Originally from Häggström M, Richfield D (2014). "Diagram of the pathways of human steroidogenesis". WikiJournal of Medicine 1 (1). <https://doi.org/10.15347/wjm/2014.005>. ISSN 20024436.

oiliness of hair and skin, and mild acne. DHEA is also used orally as a medication and dietary supplement, to restore or increase DHEA and DHEA-S levels.

Testosterone is the primary and most well-known androgen. In men, testosterone plays a key role in the development of male reproductive tissues such as the testis and prostate, as well as promoting secondary sexual characteristics such as increased muscle and bone mass, and the growth of body hair. In addition, testosterone is involved in health and well-being, and the prevention of osteoporosis. Testosterone is biosynthesized in several steps from cholesterol and is converted in the liver to inactive metabolites. It is secreted primarily by the testicles of males and, to a lesser extent, the ovaries of females. Small amounts are also secreted by the adrenal glands. Testosterone is also an anabolic steroid, which is related to growth of muscle mass and strength, increased bone density and strength, and stimulation of linear growth and bone maturation.

Testosterone levels are at their highest during adolescence and early adulthood. The first physical signs of testosterone, or androgens, in the body are apparent during puberty. A boy's voice changes, his shoulders broaden, and his facial structure becomes more masculine. But as men get older, their testosterone levels decline about 1% per year after age 30 (Table 1).

Dihydrotestosterone (DHT), or 5α-dihydrotestosterone (5α-DHT), is an endogenous androgen. The enzyme 5α-reductase catalyzes the formation of DHT from testosterone in certain tissues including the prostate gland, seminal vesicles, epididymides, skin, hair follicles, liver, and brain. Relative to testosterone, DHT is considerably more potent as an agonist of the androgen receptor (AR). During male embryogenesis DHT has an essential role in the formation of the male external genitalia, while in the adult male DHT

Table 1 Demographic distribution of testosterone level in human

Male		Female	
Age	T level (ng/dL)	Age	T level (ng/dL)
0–5 months	75–400	0–5 months	20–80

19+ years	240–950		
Average adult male	270–1070	Average adult female	15–70

30+ years – 1% per year.

This chart breaks down the normal ranges of testosterone by age and gender, according to the Mayo Clinic.

acts as the primary androgen in the prostate gland, seminal vesicles, skin, and hair follicles. It is, therefore, notorious for the prostate hyperplasia which, in turn, causes urinary obstruction in geriatric males.

Growth hormone (GH), also known as somatotropin, is a peptide hormone that stimulates growth, cell reproduction, and cell regeneration in humans and other animals. After its synthesis in the anterior pituitary gland, GH is released into the blood stream and then stimulates the liver to produce insulin-like growth factor-1 (IGF-1). IGF-1 then stimulates systemic body growth and has growth-promoting effects on almost every cell in the body, especially skeletal muscle, cartilage, bone, liver, kidney, nerves, skin, hematopoietic cell, and lungs. An animal model showed that IGF-1 promotes proliferation and migration of cavernous smooth muscle cells. IGF-1 also stimulated vascular endothelial growth factor (VEGF) secretion from cavernosal smooth muscle cells. Some clinics attempt to induce a penile enlargement by injecting recombinant human GH or IGF-1 into the corpus cavernosum, but there is no solid evidence supporting such practice.

Aldosterone is a steroid hormone produced by the zona glomerulosa of the adrenal cortex in the adrenal gland. It is essential for sodium conservation in the kidney, salivary glands, sweat glands, and colon. It plays a central role in the regulation of the plasma sodium (Na^+), the extracellular potassium (K^+) and arterial blood pressure. An in-vitro study on isolated human penile corpus cavernosal tissue showed that aldosterone has no direct contractile action or a relaxant action on human penile cavernous tissue, but acts to significantly enhance the noradrenaline-induced contraction. The effect on the noradrenaline-induced contraction is probably caused by aldosterone enhancing the affinity of the alpha-receptors for noradrenaline in isolated human penile corpus cavernosal tissue. The study suggested that aldosterone acts to enhance contraction of corpus cavernosal tissue, and is one of the restraining factors for human penile erection.

How Hormones Affect the Penis in Different Stages of Life

Prenatal Stage

In the human being, sexual differentiation is the process of developing observable traits difference on reproduction tracts between males and females. This includes the development of different genitalia and the internal genital tracts, breasts, body hair, and plays a role in gender identification. At an early stage in embryonic development, both sexes possess equivalent internal structures. These are the mesonephric ducts and paramesonephric ducts. As females have two X chromosomes, and males have one Y chromosome in addition to an X chromosome. The presence of the SRY gene on the Y chromosome causes the development of the testes in males, and the subsequent release of hormones which cause the paramesonephric ducts to regress.

By 7 weeks, a fetus has a genital tubercle, urogenital groove and sinus, and labioscrotal folds. Males become externally distinct between 8 and 12 weeks, as androgens enlarge the phallus and cause the urogenital groove and sinus to fuse in the midline, producing an unambiguous penis with a phallic urethra, and a thinned, rugated scrotum. In this stage, the role of testosterone is far smaller than that of dihydrotestosterone (DHT), and the latter will differentiate the remaining male characteristics. This reminds us that DHT plays so important role that the external genitalia can form normally and so does the prostate hyperplasia at males' early and late life respectively.

Early Infancy

In the first weeks of life for male infants, testosterone levels rise. The levels remain in a pubertal range for a few months but usually reach the barely detectable levels of childhood by 4–6 months of age. However, in this stage, no significant changes have been identified in other parts of the body.

Before Puberty

Before puberty effects of rising androgen levels occur in both boys and girls. These include adult-type body odor, increased oiliness of skin and hair, acne, the appearance of pubic hair (i.e., pubarche), axillary hair (armpit hair), growth spurt, accelerated bone maturation, and facial hair. Erection of the penis is common for a prepubertal boy, but not until puberty does an "adult type" penis growth occur.

Puberty

Pubertal effect is commonly termed pubarche which begins to occur when androgen has been higher than normal adult female levels for months or years. In males, these are usual late pubertal effects and occur in women after prolonged periods of heightened levels of free testosterone in the blood. The effects include lots of events such as growth of spermatogenic tissue in testicles, male fertility, penis enlargement, increased libido and frequency of erection, remodeling of facial bone contours in conjunction with human growth hormone, completion of bone maturation and termination of growth, increased muscle strength and mass, shoulders become broader, rib cage expands, deepening of voice, growth of the Adam's apple, enlargement of sebaceous glands, and altered body hair growth such as pubic hair, facial hair, chest hair, periareolar hair, perianal hair, and armpit hair etc.

According to the National Center for Health Statistics, the upper 95th percentile in the United States for onset age of puberty for boys is 14 (an increase in testicular size being the first sign).

Reproductive Stage

Progressive genital enlargement lasts into the third decade of life and is the result of increasing testosterone production from the testes and androgens from the adrenals. The period is characterized by an increase in the size of the penis, erections, sexual hair development, increase in muscle mass, acne, seborrhea, and a decrease in body fat.

Aging Stage

Testosterone levels reach a peak level around the third or fourth decade of life, then gradually reduce as men age. This effect is sometimes referred to as andropause or late-onset hypogonadism (LOH). Low testosterone levels can cause changes in sexual function, including reduced sexual desire, or low libido, fewer spontaneous erections, erectile dysfunction; infertility, and shrinkage of a penis. LOH is also associated with emotional changes, such as low self-confidence or lack of motivation; and physical changes, like increased body fat, reduced muscle bulk and strength, and decreased bone density.

Diagnosis and Management of Endocrine-Related Penile Conditions

Late-Onset Hypogonadism (LOH)

LOH is a clinical and biochemical syndrome associated with advancing age and characterized by typical symptoms mentioned in the previous paragraph, and most importantly, confirmed by the evidence of a low serum testosterone level. This testosterone reduction and associated symptom complex have been variously referred to as andropause, thereafter, terms of ADAM (androgen deficiency in the aging male), and PADAM (partial androgen deficiency in the aging male) are introduced.

There is a circadian variation in serum total testosterone. The blood sample should be obtained in the morning for an accurate reading.

As a man ages, the penis tends to undergo an actual reduction in size. The reduction—in both length and thickness—typically isn't dramatic but may be noticeable. If a man's erect penis is 6 in. long when he is in his 30s, it might be 5 or 5-and-a-half inches when he reaches his 60s or 70s. Atherosclerosis and fibrosis of corpus cavernosa are likely two major causes of penile shrinkage (Fig. 2). Albeit this phenomenon is not beyond controversy, it is always complained by a male whose age exceed 60 years suffers from gradual onset of penile dysmorphology associated with erectile dysfunction.

There is a strong association among age, testosterone deficiency, cavernosal fibrosis, and erectile dysfunction. Age, testosterone deficiency and cavernosal fibrosis are potentially correctable factors of cavernosal fibrosis and organic erectile dysfunction. Testosterone replacement therapy (TRT) alone or in association with phosphodiesterase-5 (PDE5) inhibitors, may lower the risk of cavernosal fibrosis or decrease the severity the fibrosis in patients with erectile dysfunction. It may resort to penile venous stripping and tunical patching reconstruction if the disease fails to be free from deterioration chronologically.

Oral testosterone supplement, transdermal delivery, and injections are available routes of TRT. Only symptomatic subjects with documented evidence of low serum testosterone levels should consider having TRT, and the patient should be well informed about benefits, goals, and precautions of TRT. During replacement therapy, key parameters including testosterone, hematocrit, hemoglobin, prostatic specific antigen (PSA), blood pressure and liver function profile should be monitored.

Delayed Puberty

Delayed puberty in boys is defined clinically by the absence or incomplete development of secondary sexual characteristics by an age at which 95% of boys have initiated sexual maturation.

Constitutional growth delay (CGD) is the most common cause of short stature and pubertal delay. Other boys with delayed puberty usually result from hypogonadism (inadequate gonadal steroid secretion) which, in turn, is most often caused by a defective gonadotropin secretion from the anterior pituitary, due to defective production of gonadotropin-releasing hormone (GnRH) from the hypothalamus.

High serum concentrations of LH and FSH are associated with various causes of gonadal disease, called primary hypogonadism and/or defects in their receptors on the membrane of the gonadal cells. Low or normal serum LH and FSH concentrations are associated with diminished GnRH-induced gonadotropin secretion, called secondary hypogonadism. This defect can be because of hypothalamic dysfunction (either anatomic or functional), hypopituitarism, hypothyroidism, or hyperprolactinemia.

Hormone therapy is reserved for patients with confirmed organic gonadotrophin deficiency (hypogonadotrophic hypogonadism), for those with a gonadal abnormality (e.g., Turner's syndrome, Klinefelter's syndrome), and for those with constitutional delay who have an abnormal psychosocial adjustment. Typically, those with constitutional delay require only a short course of intramuscular testosterone to induce puberty.

Patients with organic delay require early diagnosis and treatment to achieve normal development and optimal height and avoid issues of psychosocial adjustment with peers.

Fig. 2 Cavernosographic evidence of tunical fibrosis in geriatric males? (A) In a 65-year-old man, the plain cavernosogram (30° oblique views) was obtained when 20 mL diluted iohexol solution was injected into the corpora cavernosa via a no. 19 scalp needle. The deep dorsal vein (*white arrows*) was well demonstrated although the cavernosal veins were masked. Note that the radiolucent area (*black arrow*, inserted) was noted along the dorsal aspect of the distal corpora cavernosa. (B) An early phase of the pharmaco-cavernosograms was made 15 min after the 20 µg prostaglandin E1 was injected intra-cavernously via the same scalp needle. Again the deep dorsal vein (*white arrows*) was well shown despite the penis was in a rigid erection. No smooth lineation was noted along the distal tunica albuginea (*black arrow*, inserted) resulting from peripheral sinusoids was tethered by fibrotic tunica. Does the dorsal contour fail to preserve lineation resulting from tunical fibrosis? Note the urinary (*black asterisk*) and the enlarged prostate gland (*white asterisk*) which occupies the bladder base. (C) In a 67-year-old man, the plain cavernosogram (30° oblique views) was obtained when 20 mL diluted iohexol solution was injected into the corpora cavernosa via a no. 19 scalp needle. The deep dorsal vein (*white arrows*) was well noted although the cavernosal veins were masked. Note that the lineation of the dorsal aspect cannot be obvious. (D) Again an early phase of the pharmaco-cavernosograms was undertaken 15 min after the 20 µg prostaglandin E1 was injected intra-cavernously via the same scalp needle. The deep dorsal vein (*white arrows*) was well shown. The contour of the dorsal tunica was not lineated resulting from peripheral sinusoids was tethered by fibrotic tunica. Does the dorsal contour fail to preserve lineation resulting from tunical fibrosis? Note the urinary (*black asterisk*) and the enlarged prostate gland (*white asterisk*) which occupies the bladder base.

Congenital Adrenal Hyperplasia (CAH)

CAH refer to any of several autosomal recessive diseases resulting from mutations of genes for enzymes mediating the biochemical steps of production of mineralocorticoids, glucocorticoids or sex steroids from cholesterol by the adrenal glands (steroidogenesis).

There are six major forms of CAH, each caused by a mutation of one of the six enzymes required for the biosynthesis of cortisol. In each of these forms, the decrease in cortisol secretion results in a decrease in negative feedback at the level of the hypothalamus-pituitary. The resulting increase in adrenocorticotrophic hormone (ACTH) vs. corticotropin-releasing hormone (CRH) output attempts to return the cortisol secretion to normal if the mutation permits some degree of enzymatic activity. At the same time, the increased ACTH secretion results in a markedly elevated production of the cortisol precursors before the mutant block.

Some female infants with classic CAH have ambiguous genitalia due to exposure to high concentrations of androgens in utero. CAH due to 21-hydroxylase deficiency is the most common cause of ambiguous genitalia in genotypically normal female infants (46XX). They may be raised as boys due to enlarged clitoris mimicking penises. Less severely affected females may present with early pubarche. Young women may present with symptoms of polycystic ovarian syndrome which manifests oligomenorrhea, polycystic ovaries and hirsutism.

Males with classic CAH generally have no signs of CAH at birth. Some may present with hyperpigmentation, due to co-secretion with melanocyte-stimulating hormone (MSH), and possible penile enlargement.

Growth Hormone Deficiency and Related Conditions

Congenital GH deficiency is associated with aberrant androgen physiology and micropenis. GH replacement therapy alone can result in a catch-up in phallic size in patients with micropenis secondary to isolated congenital GH deficiency.

While for cases with GHRH (growth hormone releasing hormone) receptor deficiency, the patients have a normal penis size before puberty, whereas microphallus is typical of GH deficiency and GH receptor deficiency. Severe GH deficiency is associated with small penis size with normal penile growth at adolescence or with testosterone treatment in childhood. This is also true of GH receptor deficiency.

Adrenal Virilism or Adrenogenital Syndrome

Adrenal virilism is a syndrome in which excessive adrenal androgens cause virilization, i.e. masculinization. Diagnosis is clinical and confirmed by elevated androgen levels with and without dexamethasone suppression; determining the cause may involve adrenal imaging. There may be functioning adrenal tumors resulting in masculinization of prepubertal children. In boys, it produces a pseudo-precocious puberty. Sexual hair develops and the penis is enlarged to adult size, with frequent erections.

Treatment depends on the cause whereby adrenalectomy, removal of the causation tumor, or oral glucocorticoids for non-tumor hyperplasia is a specific option.

Congenital 5 α -Reductase Deficiency

This is an autosomal recessive intersex condition caused by a mutation in the 5 α reductase type II gene. This genetic mutation can result in pseudohermaphroditism. The condition typically presents with underdeveloped male genitalia and prostate. Males with this condition are often raised as girls due to their lack of conspicuous male genitalia. At the onset of puberty, although still in lack of DHT, their testosterone levels elevate normally. Their musculature develops like that of other male adults. After puberty, men with this condition have a large deficiency of pubic and body hair and reportedly no incidence of androgenic alopecia (pattern hair loss), and no incidence of prostate cancer.

Erection Abnormality

Geng-Long Hsu, Hsu's Andrology and National Taiwan University, Taipei, Taiwan

© 2018 Elsevier Inc. All rights reserved.

Glossary

Acquired penile deviation A condition that penile curvature results from external tethering force to penile shaft or internal fibrosis of the fibroskeleton of the penis. This term is diverted from the congenital penile deviation which develops without fibrosis within the penis.

Congenital penile deviation A status that penile curvature develops along with penile growing up at adolescence. It is always seen without remarked cause after adult life.

Erectile dysfunction A condition of inability either to attain or maintain a rigid erection for satisfactory coitus. The etiologies vary from iatrogenic to natural course including arteiogenic, neurogenic, psychogenic, pharmacologic, endocrinologic, cavernosal, and venogenic contributions.

Full erection A situation to describe a human penis attaining a complete erection. Both girth widening and length elongation are seen in addition to a rigid erection which is sustainable to buckling pressure.

Hourglass deformity A condition that a penile narrowing portion occurs in the middle penile shaft is so severe that an erectile penis looks like an hour glass.

Partial erection A situation that a penis fails to attain a complete erection resulting from internal penile structure dysfunction or external tethering limitation to the corpora cavernosa.

Penile dysmorphology A situation of the penis with a deformed shape when erection. A convertible term is a penile curvature which is a result of area differences between the convex and concave surfaces of the corpora cavernosa if bisected. It could be categorized as dorsal, ventral, left lateral, right lateral and combined types.

Peyronie's disease A chronic inflammation of the tunica albuginea of the corpora cavernosa in the human penis and also named as induratio penis plastica. It may involve the cavernosal sinusoidal trabeculae along the intracavernosal pillars while fibrotic scar initiated from the tunica albuginea. A painful erection is pronounced at earliest 3 months followed by penile deformity. Spontaneous subside may happen, however surgical intervention may require if deformity persists and interfere normal coitus.

Priapism A condition that persistent penile erection ensues despite no sexual arousal or even painful feeling which always results in detumescence.

Veno-occlusive erectile dysfunction A situation of penile venous leakage which is named to describe an inability of penile erection related veins being sealed off and consequently, fail to limit sinusoidal blood draining from the corpora cavernosa to systemic circulation in each erection bout.

Soft glans syndrome A situation complained by many males who acknowledge their glans penis is too weak to coitus. It is a general term that male subjectively feels one's glans penis being too soft. It may be inadvertently ascribed resulting from excessive drainage of penile erection related veins.

Erection Norm in Human Penis

Anatomy Reason for Penile Erectile Function and Morphology

The human penis appears to be the most peculiar organ which owns its magic extensibility resulting from the hydraulic system which, consequently, attracts most attentions in the entire human body. Albeit human penis has been in its current anatomical form for 3000 centuries, its anatomy and the erection process are still not thoroughly depicted despite extensive studies had been made. Humans penis possess an os analogue associated with some proportionally large and extraordinarily extensible corpora cavernosa which are the ideal milieu to apply Pascal's law in the entire human body if no venous leakage exists. The law depicts that pressure applied to any part of the enclosed fluid transmitted undiminished to every portion of the fluid and to the walls of the containing vessel. The erectile capability of the human penis ensues then and largely depends on sinusoids in the corpus spongiosum, the glans penis within which a distal ligament, and the corpora cavernosa, which are also responsible for erectile rigidity and erectile penile shape. It seems that the human corpora cavernosa are destined to be vulnerable to erectile dysfunction if rigidity is essential for coitus, defined as inability either to attain or maintain a rigid erection for satisfactory coitus.

Penile fibroskeleton is a determinant structure for penile morphology (Fig. 1). Recent studies substantiate a model of the tunica albuginea of the corpora cavernosa as a bi-layered structure with a 360° complete inner circular layer and a 300° incomplete outer longitudinal coat spanning from the bulbospongiosus and ischiocavernosus proximally and extending continuously into the distal ligament within the glans penis. The above two muscles, the entire outer tunica and distal ligament of the penis could be collectively categorized as skeletal components. The inner layer contains and supports the sinusoids via intracavernous pillars, the

Fig. 1 Extensibility of the fibroskeleton in the human penis. A. The tunica albuginea of the corpora cavernosa is the principal structure of the fibroskeleton in the human penis. It is a bi-layered structure in which a 360 degrees complete inner circular layer, together with the intracavernosal pillars, contains and supports the sinusoids. The extensibility of the intracavernosal pillars (upper middle) is located from 2 or 10 to 6 O'clock positions to enhances the penile rigidity when erection. It can be stretched to a thinner and green appearance (Lower, left) while the collagen type 1 act as a steel-like supporter and the intertwined collagen type 3 shows off, which mimics the erection status. In contrast, simulating a flaccid status (lower, right), its pronounced wavy appearance results from elastic fiber relaxed and the collagen type 1 stands out. (Picrosirius red, 25 $\times$).

erection-related veins, and artery which could collectively be allocated as the smooth muscle components. The delicate interplay between the vascular structures and tunica albuginea results in an erection process which is a mechanical phenomenon. The tunica outer layer plays a pivotal role in penile morphology and erection rigidity. The intracavernosal pillar is distributed between 2 or 10 to 6 O'clock positions (**Fig. 1**) in the penile pendulous portion and is commensurately abundant distally until the distal ligament meet. An abundant elastic component is characteristic for extraordinary extensibility evidenced by the flattened status (Figure, right lower) while presents markedly wavy appearance (Figure, left lower) which correspond to being stretched (erection) and tension free status (flaccid) respectively. Thus penile elongation and girth expansion occur predominantly between the retrocoronal level and penile base, we, thereafter, can acknowledge why and how the flaccid penile shape is not a matter of concern, and only erectile penile morphology is significant because satisfactory coitus requires healthy erectile function which depends upon the sinusoidal expansion. An anatomy concept is interestingly for acknowledging penile rigid erection and morphology.

Although a rigid erection of the corpora cavernosa is initiated by either central or local sexual stimuli, a local penile response is a common endpoint. Therefore, we focus on the corpora cavernosa whereby a function speaks volume. Apart from the regular vascular system for nutrition via the capillaries, there is a system for erectile function in which sinusoids shunt directly from arterial to venous channels bypassing the capillaries. The main source of blood supply to the cavernosal sinusoids originates from the internal pudendal artery (**Fig. 2**) which is the end branch of the internal iliac artery, although accessory contributions may arise from the external iliac, obturator, vesical, and femoral arteries. The internal pudendal artery gives the first branch as the bulbourethral artery which supplies the sinusoids of the corpora spongiosum. The corpora cavernosa are primarily supplied by the cavernosal artery which is the second branch of the internal pudendal artery and most distally the dorsal artery which supplies the glans and the corpus spongiosum.

The sinusoidal blood drains directly to subtunica venous plexus, subsequently passing through the tunica albuginea via the emissary veins, and then to the deep dorsal veins, cavernosal veins and para-arterial veins independently, which are collectively called erection related veins because they drain the sinusoidal blood separately. This new understanding of penile venous anatomy is highly significant. Not only do we consider the traditional deep dorsal vein significant, but also the cavernosal vein, which distributes through the entire penile length and so does the para-arterial veins. The deep dorsal vein that lies consistently in the median position receives blood from the circumflex veins of the corpus spongiosum and from the emissary veins of the corpora cavernosa. Emissary veins (**Fig. 2**) run between the inner and outer layers of the tunica for a short distance, often piercing the outer layer bundles in an oblique manner. Therefore, and significantly, these emissary veins can be easily occluded by the shearing action elicited by the inner circular and outer longitudinal layers of the collagen bundles in the tunica albuginea.

Fig. 2 Illustration of new penile vascular anatomy. (A) Lateral view: The glans penis is supported by a stout distal ligament (the *os penis* analogue) centrally just above the urethra. The DDV is consistently in the median position and receives blood of the emissary veins from the corpora cavernosa and of the circumflex vein from the corpus spongiosum. The DDV is sandwiched between the cavernosal veins (CV), but these lie at a deeper position. Bilaterally, each dorsal artery is respectively sandwiched by its corresponding medial and lateral para-arterial veins (PAVs). The pudendal artery and nerve are distributed in a similar manner but are relatively simple. (B) Cross section of the mid-penis. The corpora cavernosa is full with cavernosal sinusoids which are specific from that of the corpus spongiosum and glans penis. Note that the number of veins is seven (a larger count than the traditionally described singular vein), although it drops to four at the level of the penile hilum because each pair of the veins merges. The erection-related vasculature is arrayed in an imaginary arc on the dorsal aspect of the tunica albuginea. Thus, the penile vascular system still complies with the general rule in the body that the number of veins is normally higher than the number of arteries. Note the membranous urethra just connect the proximal end of the corpus spongiosum.

The deep dorsal vein is sandwiched by cavernosal veins that are coalesced to one at the penile base. Bilaterally each dorsal artery is sandwiched by the medial and lateral para-arterial vein respectively. Veins from the glans penis form a retrocoronal plexus that drains predominantly into the deep dorsal vein, the cavernosal veins, the para-arterial veins, the urethral veins and the corpus spongiosum respectively. The deep dorsal vein courses proximally in the midline between the paired corpora cavernosa and empties into the periprostatic plexus. The superficial dorsal vein drains the skin and the subcutaneous tissue superficial to Buck's fascia and may have direct shunts to the corpora cavernosa. This, in turn, drains into the superficial external pudendal vein. If and only if the erectile function of corpora cavernosa is healthy, the penis not only expands in its girth but also increases in its length.

Table 1 Demography of penile erection angle

Angle (degree)	Percent of population (%)
0–30	5
30–60	30
60–85	31
85–95	10
95–120	20
120–180	5

Erection Norm in Human Penis

Erection is a seamless interplay between psychologic, endocrinologic, vascular, neurologic, pharmacologic, and systemic metabolic health of the entire body. Implies a healthy erectile function depends upon the integral health of all systemic systems. However, it is not uncommon to encounter a disabled male with healthy erectile function, that is, the penile erectile function is free from disability in man suffered from spinal cord trauma. Whenever a sexual arousal ensues either from brain origin or from peripheral stimulation, a normal erection shall be subjected to a penis with healthy erectile function and ideal penile morphology. The former one is rudimentary while the latter issue is appropriate to engage in genital coitus. Therefore, we focus on the penis itself in this session. Although without a functional brain, it might be difficult to perceive sexual pleasure, in contrary, however, without a functional penis, the central order or coordination finds no effectors.

Regarding penile morphology, erection angle matters to fulfill natural coitus. Albeit sexual behavior is so individualized that there is no uniform, however, the missionary position is widely regarded as the most popular one which allows couple for close body contact and eye contact with kissing and talking throughout. Therefore, the erection angle may matter albeit it may not be a critical issue. This is the reason why there is a limited publication on penile erection angle which is more or less in normal distribution from 0 to 180 degrees (Table 1). Implies a mean may be in 90 degrees, however, clinically 120° may be more appropriate for coitus, otherwise, either a dorsal or ventral curvature should be considered. A severe ventral curvature is extraordinary awkward to do genital intercourse. Theoretically, most males are not in an ideal penile morphology. Erection angle may not be practical because it is simply a two-dimensional consideration.

Erection Dymorphology

Penile Dymorphology

An ideal penile shape is attractive to every male; however, it is very rare to encounter a perfectly ideal penile morphology in general population. Thus there is more or less a penile dymorphology which is somewhat diverted from a geometrically neutral shape. The curvature is a result of area differences (two dimensions) between the convex and concave surfaces of the corpora cavernosa if bisected. How much is the area difference in the penis with dymorphology? Given a dymorphological penis can be fixed to a perfect shape, an excision of excessive tunica or a patch to the shortage tunica is the policy of reconstruction. Excision or patching surgery results in postoperative penile shortage or elongation respectively. In order to predict how much is the area difference (Fig. 3), via a calculus or geometry method, we develop a formula which is $\pi r^2 \theta / 45^\circ$ (Fig. 3A), where r is the penile radius in centimeters, and θ is the deviation of the curvature in degrees. Clinically, r can be calculated from half of the measures between the 3 and 9 o'clock positions in centimeters when the penis is artificially erected, and θ is the estimated deviation angle in each patient. Once the two-dimensional amount is determined, the second one from goniometry, $2\pi r \theta' / \theta$ (Fig. 3B), is good to predict the length (one dimension) of area difference resulting in dymorphology. An engineering measurement can then be attainable.

Penile morphology is paramount in performing genital coitus. It is not uncommon to encounter tortured minds in many patients who had suffered from penile deformity resulting from acquired Peyronie's disease, congenital penile deviation and a variety of injury. Although the traditional anatomical paradigm of the tunica albuginea of corpora cavernosa has consistently overlooked the outer longitudinal layer which is the determined tissue of making penile morphology, the penile dymorphology must suffer victims along with human history. The penile dymorphology can be categorized to lateral, ventral and dorsal curvature in prevalent order, it can then be further assorted into left lateral, ventral, left ventrolateral, right lateral, left dorsolateral, right ventrolateral, dorsal and right dorsolateral curvature (Table 2). Thus left lateral deviation stands out followed by ventral, right lateral and dorsal curvature which is comparatively uncommon regardless it is resulting from acquired or congenital.

Penile Morphological Reconstruction

In general, the effectiveness of either medical intervention or natural morphology restoration is unpredictable although several clinical trials have been launched. Clinically varied surgical methods have been introduced in an attempt to establish an ideal penile shape in addition to erectile function restoration. The first corporoplasty was debuted in 1965. This surgical solution is followed by modified tunical excision, tunical patches and tunical plication in an attempt to make an ideal penile shape. Tunical fashion is deemed required but the plication procedure. As a rule, there is not necessary to receive corporoplasty surgery until a satisfactory

Fig. 3 Schematic illustration of discrepancy amount causing penile curvature. (A) A formula derived from calculus which is identical to that from geometry. Suppose that the center of a pipe revolves about the Z-axis by radius R as illustrated in the figure. Let S_1 and S_2 denote the outer and inner surfaces of the pipe, respectively. The difference in area between S_1 and S_2 is $S_1 - S_2 = \int_0^\pi 2\pi(R + r \sin \varphi) \cdot r d\varphi - \int_0^\pi 2\pi(R - r \sin \varphi) \cdot r d\varphi = 8\pi r^2$. Consequently, we can determine the difference in area for any degree, θ , and ΔS , which is independent of R , but dependent on the pipe radius, r , and θ : $\Delta S = \frac{S_1 - S_2}{360} \times \theta = \frac{\pi r^2 \theta}{45}$. (B) The relationship of the tunical incision sector and penile curvature degree. The incision sector (ϕ) and the curvature degrees (θ) is derived from goniometry. Seven curved penises of human cadavers with varied deviations of 20, 30, 60, 70, 90, 110, and 150 degrees respectively were collected. An 1–0 silk suture was put at the 12 o'clock position to serve as a guide of keeping the central line. The tunica was stepwise cut along the most curvilinear line until the penile shaft was straight. Subsequently, a curve of continuous parameters was then made with interpolation. The length of the patched veins required, consequently, was $2\pi r \theta' / \theta$. Note that a curved penis less than 110 degrees accounts for only approximation. Reproduction from Hsu, G. L. et al. (2006). Formulas for determining the dimensions of venous graft required for penile curvature correction. *International Journal of Andrology* 29(5), 515–520.

Table 2 The distribution of penile deformity

Direction of cure	Number (%)
Left lateral	54 (42.2)
Left ventrolateral	23 (18.0)
Left dorsolateral	5 (3.9)
Ventral	26 (20.3)
Dorsal	3 (2.3)
Right lateral	11 (8.6)
Right ventrolateral	4 (3.1)
Right dorsolateral	2 (1.6)
Total	128 (100)

coitus is severely interfered by penile dysmorphology when erection. Subsequently, tunical plication was popular owing to simplicity and reproducibility. However, postoperative outcomes were not beyond controversy and so does reliability because erectile dysfunction may result from tunical defect and dysmorphology resumption. Penile corporoplasty for mature Peyronie's disease might be a good option for this complicated disease entity. A postoperative penile shortage should be avoided by all means, which is a problem that can be solved through grafting (Fig. 4). Therefore graft surgery may be recommendable although technically challenging. Many kinds of resources have advocated, among them autologous venous material might be the material of choice for covering a corporotomy defect because it's functional and histological compatibility. Likewise, similar procedures are feasible to patients with congenital penile curvature undergoing penile corporoplasty. For anatomical consideration the deep dorsal vein and cavernosal veins were recommended although a controversy was addressed on its sufficiency, it appeared unequivocally sufficient after a scientific formula was developed, however (Fig. 3). This surgical intervention has become routine works in our practice since then. Relevant surgical solutions have been extended to use the autologous venous wall acting as the tunical inner layer (Fig. 4) and meanwhile, the porcine small intestinal submucosa functioning as the tunical outer longitudinal layer, which can achieve a prospective outcome. Of course, this challenging surgery warrants further research.

Erectile Abnormality

Pathophysiology of Erectile Dysfunction

The human erectile mechanism is an intricate interplay of hormonal, vascular, neurological, sinusoidal, pharmacological, and psychological factors, the relative influence of each respective component remains, however, somewhat unclear. What leads to an adequate erection is likely still not completely understood, with the current consensus remaining multifaceted and complex. There must be freed from a psychological disturbance, an intact neurological deficit, an imbalance hormonal profile, an adverse drug influence, a systemic disease, a dysfunctional artery and a fibrotic intracavernous tissue. Implies functional penis requires penile arterial sufficiency, normal sinusoidal tissue, and functional veins. Although there is no agreement on what would be the major contributor, there is a bias towards endothelial function due to the dramatic effects demonstrated by phosphodiesterase-5-inhibitors on erectile function.

Fig. 4 Schematic illustration of penile autologous patched surgery. (A) A retrocoronal circumferential incision is made and the prepuce is degloved. The major branch of the deep dorsal vein is readily identified with a milking manipulation. Making an appropriate opening at the exits of the emissary veins, rather than making a complete opening on Buck's fascia, is done in order to perform the pull-through maneuver of the deep dorsal and cavernosal veins. (B) Completing the pull-through maneuver requires the surgeon to make 4–5 openings. The deep dorsal vein is stripped and doubly ligated with each emissary vein. This is preserved for patch material. (C) The hydro-dissection technique is used to facilitate the intact separation, the isolation, and the tag of the neurovascular bundle. (D) An artificial erection is generated, with normal saline via a 21G or 19G scalp needle, in order to determine where the depression center is, which is feasible for an incision. Using formulas for determining the dimensions of venous graft required for penile curvature correction. (E) An incision is made with a new, sharp surgical scalpel when the neurovascular bundle is well-protected until the penis is straightened. (F) The autologous venous grafting is fashioned to the tunical defect with a running suture of 6–0 nylon. It is then enforced at each centimeter. Eventually, an artificial small intestine submucosa has used to cover the patched area to enhance the tenacity which is sustainable to intracavernous pressure.

Contrary to this, however, are recent hemodynamic studies on fresh and defrosted human cadavers whereby rigid erections were unexceptionally reproduced despite the lack of endothelial extensibility. Constant low perfusion rate was used to mimic arterial inflow, and the staged removal of erection related veins produced increasingly more rigid erections. Could it signify that those veins may, in fact, be the predominant factor that underlies erectile rigidity? Certainly, and in the light of our increased understanding of the penile vasculature, it would at least warrant re-evaluation of the role of the venous contributor for erectile dysfunction.

On penile tissue as the integral organ, the corpora cavernosa, skeletal muscle components unite smooth muscle components to meet the requirements for the erection and only allow vascular and nervous tissue to communicate with the systemic circulation system. Their anatomical relation is seems like a cluster of grape when the emissary vein is regarded as the grape trunk and each sinusoid as a fruit (Fig. 2). The rigid erection of the corpora cavernosa overall depends on cooperation among healthy sinusoids, a normal tunica, functional arteries, and competent erection related veins. Thereafter vascular dysfunction is an important cause of male erectile dysfunction. It can be classified as veno-occlusive dysfunction, arterial insufficiency, or mixed. Accordingly, the best option for restoring penile erectile function may be competence of penile erection related veins, restoration of penile arterial function and sinusoid rejuvenation.

Arterial Insufficiency

Penile arterial supply is the initial contribution of erectile function. In 1923, it was Leriche who recognized a connection between arterial insufficiency and loss of erectile function when he observed that endarterectomy of an occluded bifurcation of aorta did improve blood flow in the lower extremities and simultaneously marked the improvement of erectile capability. A dramatic enhancement of the cavernosal arterial flow is the primary initial process in obtaining a sinusoidal expansion in the paired corpora cavernosa, which is a result of smooth muscle relaxation. Any arterial lesion that compromises arterial inflow to the penis can lead to erectile dysfunction; this is particularly true for lesions in specific arteries such as the cavernosal and dorsal artery.

It is commonly agreed that the prevalence of the arterial disease increases with age and subsequently is a major cause of organic erectile dysfunction in men over the age of 50. Consensus shows that erectile dysfunction seems to be a bellwether for a development of coronary artery disease in asymptomatic men, and both diseases share the same medical conditions and risk factors such as diabetes mellitus, hypertension, hypercholesterolemia, hyperlipidemia and smoking habit etc. Of course, erectile dysfunction can be due to atherosclerotic or traumatic arterial occlusive disease. Furthermore, in arteriogenic erectile dysfunction, the corpora cavernosa shows lower oxygen tension, which, in turn, may result in a decreased volume of sinusoidal smooth muscle and subsequent venous leakage, ensues. In an experimental animal model, rabbits with iatrogenic iliac atherosclerotic disease demonstrated alterations in their downstream penile arteries and a reduction in cavernosal smooth muscle content. The pathogenesis of erectile dysfunction in these patients is likely to be related to endothelial dysfunction. These alterations were associated with decreased nitric oxide synthase (NOS)- and NO-mediated relaxation of sinusoidal tissues in the corpora cavernosa. In those whose erectile dysfunction is owing to traumatic stenosis of pudendal or cavernous arteries has been noted in young men with long-distance cyclists or pelvic trauma, the ultimate goal of the arterial reconstruction is to provide an alternative arterial pathway to bypass arterial lesions that cause obstruction in the hypogastric-cavernous arterial bed, and offers an option for potential cure.

Veno-Occlusive Dysfunction

This may be specific to excessive venous drainage. Early detumescence and insufficient rigidity are the common symptoms. In 1873, the Italian Francesco Parona injected varicosity dorsal penile vein of an impotent young patient with hypertonic saline in order to cause sclerosis and subsequently reduce the excessive venous outflow. Subsequently, the concept that erectile disorders might be treated surgically by occluding venous channels from the penis was materialized as early as the turn of the 20th century such as Henry Raymond, James Duncan, Joe Wooten and Frank Lydston in 1895, 1895, 1902, and 1908 respectively. Exemplified in 1902, Joe Wooten suggested, as a justification for this type of surgery, the hypothesis of atonic impotence, claiming that it is the result of the loss of smooth muscle tonicity in the corpora cavernosa, resulting in dilated veins and sinusoids at that level. Later in 1908, Frank Lydston published his results on 100 venous ligation procedures reporting that 50% of his patients were definitely cured and that the rest had improved their sexual function. Lydston claimed, as an explanation for these good results that he ligated not only the superficial dorsal vein but also the deep dorsal vein of the penis, as well as collateral veins, courting penile tumescence, along with a sensation of enlargement of the penis which boosted the psychological confidence of patients in the effectiveness of this technique.

Beginning in the 1930's Oswald Swinney Lowsley combined simple dorsal vein plication with a surgically more advanced perineal crural technique in which he plicated the bulbocavernosus and ischiocavernosus muscles with several mattress sutures. After his initial report in 1935, he could follow-up 273 patients of the more than 1000 patients operated upon in his later publication from 1953. Afterward, as urologists embraced different techniques of vascular surgery and transplantation, attempts to resolve erectile dysfunction were directed towards the possibility of producing a greater blood supply through arterial revascularization techniques and meanwhile limiting venous drainage through venous ligation. These techniques of venous surgery disappeared from medical literature until in the 1980's the rebirth of venous surgery took place as a result of the new field of investigation of erectile physiology.

Unfortunately, a severe restraint of penile venous surgery for treating erectile dysfunction has been recommended since 1996 thus far. Every treatment modality must be somewhat effective; otherwise, repeated experiments would not be performed on the human body. This principle is applicable to all methods of penile venous surgery. It justly deserved to be condemned and abandoned if its erection restoration outcome is disappointing and it is seemingly unavoidable on adverse side effects, such as irreversible deformity and permanent penile numbness. Despite these drawbacks, our method of penile venous stripping with venous ligation is performed at the exits of emissary just closest to the outer tunica has been developed with the inspiration of patients' positive response in tandem with the advances of penile tunical and venous anatomy associated with the erection mechanism since 1986. We applied a refined penile venous stripping in many thousands of patients under acupuncture-assisted local anesthesia on an outpatient basis. It ultimately won the USPTO (The United States Patent and Trademark Office) patent on August 14, 2012. Although currently, we recommend penile venous stripping to patients who are nonresponders to phosphodiesterase-5 (PDE-5) inhibitors, we always fail to decline patients who are recommended by operated patients.

The problem is how to identify those offensively veins? Recently, computerized tomography-cavernosography is advised to be most advanced, however, after our chronic observation; it appears that the penile venous anatomy per se is only demonstrable via a pilot set of cavernosography and the veno-occlusive dysfunction physiology is appropriately documented via pharmacocavernosography (cavernosograms after working of intracavernously injected vaso-active agent such as prostaglandin E1). Those offensive veins can be enhanced visible once via squeezing manipulation after larger veins are shuttled down. Totally the ligation sites up to 132 positions. Albeit it seems technical challenging, this innovative method turns the venous surgery for treating erectile dysfunction from one that has been abandoned to a curable option because its prototype has been sustainable since 1986.

The current consensus of most urologists is that ED is due to the cavernosal factor, an inability to achieve a rigid erection is attributed to the loss of smooth muscle relaxation and fibrous compliance. We observed in our study, however, that reaching a rigid erection was actually a hemodynamic phenomenon, in which Pascal's law could be applied to be performed. We then shifted our focus to fresh cadavers with inspiration drawn from the trauma history gained during World War II by Newman HF. It was discovered then that the corpora cavernosa was easily accessible for the purpose of blood transfusion in emergency situations where no peripheral vein was available. Amazingly, a rigid erection ensued regardless of the absence of vital signs in a wounded soldier when the transfusion speed exceeded 25 mL/min. After penile venous stripping, the induction flow was notably less than prior to removal. The maintenance flow of most subjects was also much lower than the normal arterial in attaining a sufficient erection, thereafter, the role of venous surgery in treating erectile dysfunction deserves reevaluated? Although venous surgery for erection dysfunction has been criticized for not being durable, the recurrence of sexual inadequacy on operated patients, however, has not been supported by any evidence of regeneration of the venous vasculature. Accordingly our chronological research and clinical application for over three decades, we found that not only the veno-occlusive dysfunction is the predominant cause of erectile dysfunction, but also the penile venous stripping is categorically a viable option at a negligible complication at an ambulatory basis. In contrast, an obstructive penile venous drainage is also a severe medical problem. It is renowned as a condition of priapism which the penile venous drainage is significantly hindered resulting from sickle cell anemia or straddle injury, which will be illustrated more.

Clinical Relevance Erection Abnormality

Disease of Venous Drainage Blockage

In a normal situation, the penile detumescence occurs when cavernous blood dissipates via erection related veins after an erection bout. A priapism develops resulting from persistent, over 6 h, a penile erection occurs if venous drainage is compromised despite no sexual desire or even painful suffering. It may be induced by drug, trauma or disease such as leukemia and sickle cell anemia. It is commonly classified into ischemic, nonischemic and recurrent ischemic types. The most common one is ischemic priapism which happens when blood does not adequately drain away from the corpora cavernosa. The penile erection veins are not completely blocked in the nonischemic priapism which is typically resulting from a shunt formed between the corpus spongiosum and an artery or disruption of the nerve of parasympathetic nervous system.

Medical history and physical examination is the first impression of the priapism and then is further documented by sonography and cavernosal blood gas analysis. The most common cause of ischemic priapism is sickle cell disease followed by medication such as selective serotonin reuptake inhibitor, cocaine, and cannabis, intracavernous injection agent including papaverine and prostaglandin etc. Ischemic priapism is typically advised with a nerve block for pain relief followed by aspiration of blood from the corpus cavernosum. A cavernosal measurement is an advice by cold normal saline irrigation or phenylephrine injection if no obvious effectiveness, whereas nonischemic priapism is often treated with cold packs and compression. Shunting surgery may be required if usual measures are not effective. Priapism may lead to permanent fibrosis of the corpora cavernosa so severe that it sustains an erectile dysfunction or penile dysmorphology.

Disease of Penile Excessive Venous Drainage

Excessive penile venous drainage appears to be the most popular etiology resulting in erectile dysfunction. Penile veno-occlusive dysfunction is newly termed instead of venogenic erectile dysfunction or penile venous leakage, new treatment modality is limited but the first line usage of phospho-di-esterase-5 inhibitor. In young males younger than 40 years, it is unexceptionally noted to have

excessive venous drainage veins once psychological influence is ruled out. Unfortunately, they are always refractory to phosphodiesterase-5 inhibitors. Their symptoms include insufficient rigidity, early detumescence, loss of morning erection, position dependent impotence, soft glans syndrome and gradual onset of early ejaculation.

Since 1986 we have successfully treated many hundreds of young males who suffer from venous leakage, this denotes that venogenic erectile dysfunction is real and the current medical community should reevaluate this disease rather than just ignore this disease entity. The corpora cavernosa is nutritious with blood and susceptible to the rapid development of the venous drainage speed to override the penile arterial supply. Therefore it is understandable to acknowledge the controversial disease.

Disease of Penile Arterial Insufficiency

A functional penile artery is a prerequisite for erectile function. Similar to other kinds of cardiovascular disease, arterial vasculogenic causes of erectile dysfunction increase with age and are most prevalent in those with risk factors for atherosclerosis such as diabetes, hypertension, hyperlipidemia, smoking, and obesity. Traumatic events, which occur more often in younger men, are due to pelvic and/or perineal trauma. Arterial insufficiency can be detected using color Doppler ultrasonography, if the peak systolic velocity is less than 25 cm/s. Angiography, while being the benchmark for all arterial investigations, is reserved with the aim of concurrent arterial revascularization or angioplasty if a penile arterial stenosis is suspected. Recently a penile arterial stent is revisited with a controversial result.

Diseases of Corporeal Fibrosis

Corporal fibrosis usually occurs after Peyronie's disease, refractory low-flow priapism, the chronic intracavernous injection of vasoactive drugs, explantation of an infected penile prosthesis and severe penile trauma etc. Peyronie's disease is a connective tissue disorder which involves the tunica albuginea. It is commonly ascribed to repeated microtrauma on the tunica albuginea and sinusoidal tissues, which extends to involve the corporeal body. Specifically, scar tissue tethers sensation nerve will cause pain which may last for the first 3 months and then reach a mature stage in 1 year. It always present with erection dysfunction, loss of girth and penile length, penile dysmorphology and even hourglass deformity. A variety of treatments have been used, but none have been especially effective. Tunical patch surgery may be required if it is refractory.

Ejaculation/Semen

Pierre Clément, Université de Versailles-Saint Quentin en Yvelines, Montigny le Bretonneux, France

© 2018 Elsevier Inc. All rights reserved.

Introduction

Ejaculation comes from the Latin word 'ejaculari' meaning to project, to throw forcefully. Then, ejaculation can be defined as the forceful propulsion of semen out of the body. Because ejaculation occurs in a sexual context in response to a combination of brain (visual, auditory, olfactory, and fantasy) and peripheral (penile and erogenous zones) stimuli, the term ejaculatory response is sometimes read in scientific/medical texts. The primary objective of ejaculation is to allow the male to deliver its gametes (i.e. spermatozoa) for fertilization of the female mature reproductive cell (i.e. ovum). Ejaculation appeared relatively early in the evolution of living species as an effective mean of reproduction and many aspects of the ejaculatory response are common to a number of animal species, from reptiles to mammals. The ejaculatory response is characterized by the synchronized succession of physiological events that form two distinct phases that are emission and expulsion. Emission is the secretion of the spermatozoa from testes (more exactly from epididymis) together with different components of the seminal fluid produced by accessory sex glands. Mixing of all the elements of the semen takes place in the part of the urethra surrounded by the prostate (i.e. prostatic urethra). Once emission phase is completed, expulsion is triggered that occurs in form of intense rhythmic contractions of several pelvic striated muscles that led to forceful expulsion of semen through the urethral meatus.

Semen

Semen is composed of spermatozoa and fluid synthesized and secreted by the sex glands that contribute to ejaculation. Semen contains a variety of enzymes, sugars, lipids, oligo-elements, and other substances which provide the male gametes with a nutritive and protective milieu. Due to the anatomical arrangement of the ejaculatory tract, the components of the seminal fluid are deposited into the prostatic urethra sequentially. As a result, ejaculate (i.e. expelled semen) is divided in portions characterized by differences in their composition and function. The first portion of the ejaculate consists of a small amount of fluid from the bulbourethral glands and is usually lacking spermatozoa. It contains mucus, acid phosphatase, and sialic acid that contribute to lubrication, semen coagulation, and neutralization of the acidity of urethral and vaginal environment. The second portion of the ejaculate is characterized by a low-viscosity opalescent fluid released from the prostate. A few spermatozoa are found in this fraction which is richer in sugars, organic acids, fibrinolysin, proteolytic enzymes, and zinc (chromatin stabilizer). Then the principal portion of the ejaculate is expelled which contains the highest concentration of spermatozoa, along with secretions from the epididymis, and vas deferens, as well as prostatic and seminal vesicle fluids. This fraction contains amino acids, vitamins, mucus, fructose (the main source of energy for spermatozoa), and prostaglandins (immunosuppressive action). A last fraction can be distinguished that consists of seminal vesicle secretions. In sexually mature men, the volume of seminal fluid varies between 0.1 and 10 mL and contains an average of 30.10^6 spermatozoa per mL. Semen volume depends on multiple factors and on the time elapsed from the previous ejaculation.

Anatomy

Detailed anatomical description of the genital tract is provided in other sections of this volume. Here, a brief overview of the organs and anatomical structures participating to the ejaculatory response (i.e. ejaculatory tract) is given. The organs that contribute to the emission phase of ejaculation synthesize, secrete, and/or discharge the different components of the seminal fluid.

- Epididymis: located posterior to the testis, the epididymis is the site where spermatozoa undergo final maturation and are stored prior to be transported onward into the urethra through the vas deferens.
- Vas (or ductus) deferens: as emission occurs, smooth muscle cells in the wall of the vas deferens strongly contract that allow spermatozoa to rapidly reach the prostatic urethra. Before joining the urethra, the vas deferens widens to form the ampulla of the vas deferens that lies close to the seminal vesicle.
- Seminal vesicles: composed of epithelial cells, which produce 50%–80% of the total volume of seminal fluid. Epithelium is surrounded by smooth muscle cells, which contraction during emission discharges the content of the gland into the prostatic urethra (Fig. 1).
- Prostate: single gland surrounding the urethra immediately below the bladder. It is composed of alveolar epithelium, which secretes 15%–30% of the total volume of seminal fluid, and fibromuscular tissue which contracts as emission occurs to pour prostatic fluid into the prostatic urethra. The openings of the ejaculatory ducts (ampulla of the vas deferens, ducts of the seminal vesicles and prostate) are found on the dorsal side of the urethra and form a particular structure, the veru montanum, which prevents seminal fluid to go backward into the ducts during the expulsion phase of ejaculation.

Fig. 1 Peripheral events of emission and expulsion phases of ejaculation. During emission, bladder neck and external urethral sphincter are closed and secretions from sex glands (seminal fluid + spermatozoa) are poured into the prostatic urethra where they accumulate. During expulsion, bladder neck remains closed, external urethral sphincter is opened, and rhythmic contractions of bulbospongiosus muscle forcefully propelled semen throughout the urethra.

- Bulbourethral glands (or Cowper's glands): pea size paired glands closely invested by a layer of striated muscle. They produce a very small amount of seminal fluid (<5% of the total volume) which is discharged into the penile portion of the urethra, downstream of the prostatic urethra.

Intense and rhythmic contractions of muscles and anatomical structures participating to expulsion led to forceful propelling of semen in anterograde direction, through the urethral meatus (**Fig. 1**).

- Bladder neck (or internal urethral sphincter): is composed of smooth muscle cells that firmly contract during expulsion to avoid semen to flow backward into the bladder.
- Urethra: the urethra epithelium is surrounded, over about half of its length, by circular striated muscle forming the external urethral sphincter (or rhabdosphincter). This sphincter rhythmically contracts during the expulsion phase to help semen to move forward.
- Pelvipereineal striated muscles: include levator ani, ischiocavernosus and bulbospongiosus muscles, with the latest having a preponderant role. As expulsion occurs, the rhythmic and intense contractions of these muscles are essential in forceful propelling of semen throughout the urethra and are responsible for saccadic expulsion of semen out of the body.

Peripheral Response

Innervation

Sensory afferents

Sensory receptors stimulated during coitus or masturbation are essentially located in the penile skin, prepuce, and glans. Sensory inputs are conveyed to the upper sacral and lower lumbar segments of the spinal cord via the dorsal nerve of the penis, a sensory branch of the pudendal nerve (**Fig. 2**). A relatively sparse sensory innervation of ductus deferens, prostate, and urethra has also been described which reaches the lumbosacral spinal cord via the pudendal nerve. A second afferent pathway is constituted by fibers traveling along the hypogastric nerve and, after passing through the paravertebral lumbosacral sympathetic chain, enters the thoracolumbar segments of spinal cord (**Fig. 2**). Sensory afferents terminate in the medial dorsal horn and the dorsal gray commissure of the spinal cord.

Motor efferents

Cell bodies of the preganglionic sympathetic neurons are located in the intermediolateral cell column and in the central autonomic region of the thoracolumbar segments of the spinal cord. The majority of sympathetic fibers relay in the paravertebral sympathetic chain and continue through the splanchnic nerve to reach the inferior mesenteric ganglia. Arising from the inferior mesenteric ganglia is the hypogastric nerve that forms, after joining the parasympathetic pelvic nerve, the pelvic plexus from which arise fibers innervating the ejaculatory tract (**Fig. 2**).

Cell bodies of the preganglionic parasympathetic neurons are located in the intermediolateral cell column of the lumbosacral segments of the spinal cord in an area referred to as the sacral parasympathetic nucleus. Neurons of the sacral parasympathetic nucleus send projections, via the pelvic nerve, to the postganglionic neurons located in the pelvic plexus (**Fig. 2**).

Fig. 2 Schematic view of the autonomic and somatic innervation of genitalia. Neural pathways involved in ejaculation are indicated. *DNP*, dorsal nerve of the penis; *DRG*, dorsal root ganglia; *HN*, hypogastric nerve; *PN*, pelvic nerve; *PP*, pelvic plexus; *PudN*, pudendal nerve; *SGE*, spinal generator of ejaculation. Reprinted from Handbook of Clinical Neurology, vol.130, P. Clement and F. Giuliano, Anatomy and physiology of genital organs – men, pp. 19–37, 2015, with permission from Elsevier.

Cell bodies of the motoneurons are found at the lumbosacral spinal level in the Onuf's nucleus, exit the ventral horn of the medulla and proceed via the motor branch of the pudendal nerve to the pelvic floor striated muscles, including bulbospongiosus-muscle (Fig. 2).

Physiology

Activation of sympathetic, parasympathetic, and somatic divisions of the nervous system occurs in synchrony during ejaculation. In addition, the non-adrenergic non-cholinergic (NANC) system also contributes to the control of ejaculation through modulation of sexual glands.

Based on the innervation of the male genitalia, it is proposed that parasympathetic tone controls epithelial secretion in sexual glands while sympathetic tone controls contractile activity of the smooth muscle cells composing sexual glands and related ducts. Clinical observations confirmed the essential role of sympathetic pathways supplying the urogenital region in men. Notably, disruption of sympathetic nerves in patients who underwent retroperitoneal lymphadenectomy for surgical treatment of testicular cancer suffer ejaculatory dysfunctions. Accordingly, surgical approaches that spare sympathetic innervation reduce the incidence of ejaculatory dysfunctions in these patients. Electrical stimulation of the hypogastric plexus, which harbors postganglionic sympathetic neurons innervating the urogenital area, triggers emission of semen in paraplegic men unable to ejaculate during sexual intercourse. Saccadic expulsion of semen is caused by synchronized contractions of pelvipereineal striated muscles and external urethral sphincter, with a key role for the bulbospongiosus muscle. Activity of these muscles is characterized by intense and short bursts of contraction that are not under voluntary control, explaining that expulsion is regarded as a reflexive event. Genital sensory innervation including sensory receptors in the penis (skin, prepuce, and glans) has a crucial role in ejaculation. In humans, different modes of penile stimulation can elicit contractions of bulbospongiosus muscle. This led to the development of clinical procedures for evaluation of neural pathways controlling ejaculation and for triggering ejaculation.

Neurochemistry

Noradrenaline and acetylcholine

There is a dense autonomic (both sympathetic and parasympathetic) innervation of the male genitalia. Sympathomimetic agents, which mimic in part the action of noradrenaline, have been shown to cause seminal tract and sexual glands contractions. The effect is mainly mediated by α -1 adrenoreceptor subtypes that are expressed by smooth muscle cells. Cholinomimetic agents, which partially reproduce the activity of acetylcholine, can also elicit contractions of sexual glands through activation of muscarinic receptor subtypes. Moreover, stimulation of muscarinic receptors triggers seminal fluid secretion from seminal vesicles.

Nitric oxide

Nitric oxide (NO) fibers are a major component of the NANC system and have been detected in the entire seminal tract in the man. In vitro functional investigations on human seminal vesicles indicate that NO exerts an inhibitory effect on smooth muscle contractile activity.

Oxytocin

Oxytocin (OT) is a hormone produced predominantly by the pituitary gland and also, in a lower amount, by testes and prostate. Oxytocin induces contraction of smooth muscle cells in sexual glands through direct and indirect mechanisms and was suggested to promote spermatozoa transport in the vas deferens (Filippi et al., 2002).

Sensory receptors

The crucial role of penile sensory stimuli in the ejaculatory response is best illustrated by the effect of topical anesthetics. Combination of lidocaine and prilocaine and extract from Asian natural herbs were reported to significantly increase ejaculation latency in men diagnosed with premature ejaculation following application on the penile glans (Xia et al., 2013).

Spinal Control

The Spinal Network of Ejaculation

A neuronal circuitry exists in the spinal cord that controls ejaculation. This circuitry includes groups of neurons lying in different spinal cord segments (Fig. 3). Sympathetic preganglionic neurons innervating the urogenital area are located in the intermediolateral cell column and the dorsal gray column of thoracolumbar (12th thoracic-2nd lumbar) spinal segments. Preganglionic

Fig. 3 Schematic view of the spinal network of ejaculation. The spinal generator of ejaculation (SGE) projects to: (i) thoracolumbar sympathetic centers including dorsal gray column (DGC) and intermediolateral nucleus (IML), (ii) lumbosacral parasympathetic centers including sacral parasympathetic nucleus (SPN), (iii) lumbosacral somatic centers including Onuf's nucleus. Those autonomic and somatic spinal centers control seminal tract and perineal striated muscles. Reprinted from Handbook of Clinical Neurology, vol.130, P. Clement and F. Giuliano, Anatomy and physiology of genital organs – men, pp. 19–37, 2015, with permission from Elsevier.

parasympathetic neurons sending projections to the urogenital area form the sacral parasympathetic nucleus that is located in the intermediolateral cell column of sacral segments (2nd sacral - 4th sacral). Somatic motoneurons supplying pelvic perineal striated muscles and urethral sphincter are found in a single nucleus (namely Onuf's nucleus) in the ventral horn of S2-S4 segments. Finally, a group of spinal interneurons has been identified to play a role of generator of ejaculation (Chehensse et al., 2017; Truitt and Coolen, 2002). Peripheral and cerebral sexually relevant stimuli are summated in the spinal generator that, once the excitatory threshold is reached, triggers synchronized activity of autonomic and somatic neurons belonging to the spinal network of ejaculation. A key component of the spinal generator of ejaculation (namely lumbar spinothalamic neurons) has been characterized around the central canal in lumbar (L3-L4) segments. Lumbar spinothalamic neurons project to preganglionic autonomic neurons innervating the sexual glands and to motoneurons innervating bulbospongiosus muscle (Fig. 3). Integrity of the spinal network is sufficient for ejaculation to occur as evidenced in rats with thoracic spinal segment sectioned (Borgdorff et al., 2008). In man, the existence of a spinal generator of ejaculation has recently been evidenced based on clinical and neurohistochemical investigations. It was reported that lesion of L3-L5 spinal segments is correlated with the inability of spinal cord injured patients to ejaculate during sexual intercourse (Chehensse et al., 2017).

Neurochemistry

GABA

The neurotransmitter γ -aminobutyric acid (GABA) is widely distributed in the central nervous system and virtually influences all centrally driven neurophysiological processes. Baclofen, an antagonist of GABA-B receptor subtypes, is delivered in the subarachnoid space to alleviate refractory spasticity in patients with spinal cord injury or multiple sclerosis. Clinical observations showed that intrathecal injection of baclofen altered the ability of these patients to ejaculate (Denys et al., 1998). Experimental investigations provided clarification on GABA mechanism of action by demonstrating that blockade of GABA receptors in the spinal generator of ejaculation inhibited ejaculation (Borgdorff et al., 2008).

Oxytocin

Neurons located in the hypothalamus send projections containing oxytocin onto the autonomic neurons (both sympathetic and parasympathetic) innervating the urogenital tract. Antagonists of OT receptor inhibit the ejaculatory response in a model of pharmacologically induced ejaculation (Clement et al., 2013). It is then postulated that descending oxytocin hypothalamic neurons modulate the spinal mechanisms of ejaculation.

Serotonin

Autonomic and somatic spinal ejaculatory centers receive multiple serotonin (5-HT) projections from several brain origins. The fact that various 5-HT receptor subtypes exist in the spinal ejaculatory centers with different cellular location (pre/postsynaptic, auto/heteroreceptors) and pharmacodynamic properties (ligands affinity, activatory/inhibitory) makes it difficult to understand the exact role of spinal 5-HT in the control of ejaculation. From a series of pharmacological studies using different experimental models and providing apparently conflicting results, it can be concluded that 5-HT exerts a multilevel and multimodal action in spinal mechanisms of ejaculation (triggering/facilitation of ejaculation, inhibition of expulsion; for details see Giuliano and Clement, 2012).

Substance P

The crucial role of genital sensory stimuli in ejaculation has been mentioned earlier in the text. One neurotransmitter involved in the transmission of sensory information from the periphery to the spinal cord is substance P which is produced by primary sensory neurons. The receptor for substance P (neurokinin-1; NK1) is expressed in the spinal generator of ejaculation. The selective neurotoxic lesion of NK1-expressing lumbar spinothalamic neurons resulted in suppression of ejaculation with no alteration of other sexual responses in male rat free to copulate (Truitt and Coolen, 2002).

Other neurotransmitters

Neurochemical characterization of the spinal ejaculatory network led to the identification of other factors including cholecystokinin octapeptide fragment, galanin, gastrin releasing peptide, and endogenous opioid peptide enkephalin (reviewed in Giuliano and Clement, 2012). However, functional evidence is scarce and the respective role of those factors is poorly understood. Of interest is the pharmacological study showing the pro-ejaculatory action of agonist of receptor for gastrin releasing peptide in the rat (Sakamoto et al., 2008).

Brain Control

The Brain Network of Ejaculation

The existence of a neuronal circuitry in the brain specifically controlling ejaculation has been demonstrated experimentally that is part of larger network involved in the regulation of the sexual response (Giuliano and Clement, 2012; Veening and Coolen, 2014). This cerebral network is composed of several interconnected groups of neurons distributed in several divisions of the brain in sensory/integrative, excitatory, and inhibitory areas (Fig. 4). The posteromedial division of the bed nucleus of the stria terminalis,

Fig. 4 Diagram of brain structures and central pathways involved in ejaculation. *BNSTpm*, posteromedial bed nucleus of stria terminalis; *MeApd*, posterodorsal medial amygdaloid nucleus; *MPOA*, medial preoptic area; *PAG*, periaqueductal gray; *nPGi*, paragigantocellular nucleus; *PNpd*, posterodorsal preoptic nucleus; *PVN*, paraventricular thalamic nucleus; *SPFP*, parvicellular part of the subparafascicular thalamus.

the posterodorsal area of the medial amygdala, the posterodorsal preoptic nucleus, and the parvicellular part of the subparafascicular thalamus contain group of neurons that were found activated concomitantly to ejaculation. In addition, the subparafascicular thalamus receives direct projections from lumbar spinothalamic neurons, the essential component of the spinal generator of ejaculation. The above brain structures are involved in the integration and processing of sexually-relevant stimuli including sexual cues and peripheral somatosensory stimuli. Brain structures containing neurons that send excitatory signals to the spinal network of ejaculation have been identified. One pathway includes neurons in the medial preoptic area that project onto neurons of the paraventricular hypothalamic nucleus which in turn send axons to autonomic neurons belonging to the spinal centers of ejaculation (Fig. 4). Another excitatory pathway consists in neurons located in the lateral hypothalamus and directly contacting lumbar spinothalamic neurons (Facchinetti et al., 2014). Finally, the source of inhibitory tone on the spinal command of ejaculation has been found in a number of nuclei in the ventral medulla (Fig. 4). Gigantocellular nuclei and ventral raphé nuclei directly project onto autonomic and somatic spinal ejaculatory centers as well as lumbar spinothalamic neurons. In view of the complexity of the brain ejaculatory network and the variety of descending pathways, a multilevel and multimodal control on spinal executive mechanisms of ejaculation is evident.

Non-invasive neuroimaging technologies allow the detection of brain areas that are activated or inhibited (in comparison with a standardized basal condition) in relation with a controlled experimental situation. A few studies conducted in healthy male volunteers led to the identification of intense neuronal activation in relation with ejaculation in the mesodiencephalic transition zone, in the thalamus in regions including medial, ventral, and subparafascicular thalamic subareas, as well as in the parietal cortex (Arnou et al., 2002; Holstege et al., 2003). The latter is considered as a site which processes sensory information. However, because ejaculation is a brief phenomenon and part of a global sexual response, the limited temporal resolution of functional imaging techniques makes it difficult to discriminate brain regions specifically activated during ejaculation.

Neurochemistry

Serotonin

The role of cerebral 5-HT in the control of the ejaculatory response has received particular attention. Selective 5-HT reuptake inhibitors (SSRIs) are widely prescribed as antidepressants and have long been associated with sexual side effects including delayed ejaculation. On this basis, new therapeutical approach of premature ejaculation was developed and eventually led to the registration

of the first agent (dapoxetine) in this indication. The blockade of 5-HT transporters by SSRIs results in increased 5-HT extracellular levels and, consequently, in enhanced 5-HTergic neurotransmission in the CNS. The increased 5-HT tone is suggested to be the mechanism by which SSRIs lengthens ejaculation latency (Giuliano and Clement, 2012). The mode of action of brain 5-HT in the control of ejaculation has been extensively studied in laboratory animals. An opposite action of 5-HT on sexual behavior and more particularly ejaculatory behavior was reported in male rats depending on the site where 5-HT is microinjected (Hull et al., 2004). Delivery of 5-HT into 5-HTergic projection areas (forebrain, medial preoptic area) delayed or inhibited ejaculation whereas delivery into sites containing 5-HTergic neuron cell bodies (raphe nuclei) facilitated ejaculatory behavior. As aforementioned, a comprehensive view of the role of 5-HT is complicated by the variety of receptor subtypes expressed in the CNS. Ligands of 5-HT_{1A}, 5-HT_{1B}, and 5-HT_{2C} receptors have been tested in different animal paradigms (Giuliano and Clement, 2012; Hull et al., 2004). Stimulation of 5-HT_{1A} receptors enhanced ejaculatory behavior in the male rat. This receptor subtype is a somatodendritic autoreceptor (i.e. expressed on cell bodies of 5-HT neurons) which activation turns down firing of 5-HT neurons and, as a consequence, decreases 5-HT release. Then, pro-ejaculatory action of 5-HT_{1A} agonists may be explained by reduction of the 5-HTergic inhibitory tone on CNS ejaculatory mechanism. Stimulation of 5-HT_{1B} receptors resulted in inhibition of ejaculation in the male rat. Although, because these receptor subtypes can be presynaptic autoreceptors or postsynaptic heteroreceptors, the exact modality of 5-HT_{1B} involvement is still unclear. Finally, it was reported that stimulation of 5-HT_{2A/C} receptors inhibited ejaculatory behavior in the male rat.

Dopamine

Another neurotransmission system that has been widely explored is the dopaminergic system, and more particularly the incerto-hypothalamic pathway (Hull et al., 2004; Peeters and Giuliano, 2008). The dopaminergic incerto-hypothalamic pathway is composed of neurons which cell bodies are in the medial zona incerta and in the periventricular nucleus and which terminals are in the hypothalamus (including lateral and medial preoptic areas, and parvocellular division of the paraventricular nucleus), the thalamus and the midbrain. Dopamine has a pro-ejaculatory activity and the medial preoptic area is a key component of the incerto-hypothalamic pathway in mediating this effect. It has long been unclear which dopamine receptor subtypes were involved as availability of selective pharmacological ligands was limited. The dopamine D₂-like receptors, which include D₂, D₃, and D₄ subtypes, were found implicated but it is only recently that the crucial role of D₃ receptors was revealed in the male rat by the use of highly selective D₃ antagonist (Clement et al., 2009). Based on observations of anejaculation in schizophrenic patients treated with antipsychotics (antagonists of D₂-like receptors), the antipsychotic levosulpiride was tested in men with premature ejaculation and was reported to lengthen ejaculation latency.

Oxytocin

Oxytocinergic parvocellular neurons in the hypothalamic paraventricular nucleus project in multiple areas in the CNS, including brain structures belonging to the brain network of ejaculation (bed nucleus of the stria terminalis, medial amygdala, and medial preoptic area). Stimulation and blockade of brain oxytocin receptors respectively facilitated and inhibited ejaculatory behavior in the male rat (Arletti et al., 1985; Clement et al., 2013). Direct action on oxytocinergic pathway and modulation of 5-HT and dopamine neurotransmission are possible mechanisms mediating oxytocin receptor ligands effect on the ejaculatory response. In human however, a recent clinical trial failed to reveal a significant effect of oxytocin antagonist on delay to ejaculate in premature ejaculation patients.

Other neurotransmitters

Neuroanatomical and functional investigations have been conducted in order to define the role of other neurochemical factors participating to the cerebral control of ejaculation (Giuliano and Clement, 2012). Notably, evidence have been gathered in the male rat showing the inhibitory effect of endogenous opioids and agonists of opioid receptors (mainly μ subtypes). In man with premature ejaculation, the opioid analgesic tramadol has been reported to be an effective on-demand treatment. The efficacy of tramadol is certainly explained by a dual action on opioid receptors (preferential agonist for μ receptors) and 5-HT transporter (inhibitor). Finally, immunohistochemical studies have detected a number of neuropeptides in the rat brain circuitry of ejaculation. Among them, cholecystokinin, galanin, and tuberoinfundibular peptide 39 have been found in pivotal brain structures although their respective role in the control of the ejaculatory process remains to be clarified.

Conclusion

Ejaculation is a short-lasting physiological event and is part of a more global sexual response that includes sexual desire, arousal, and erection. The discrimination of the physiological and pharmacological mechanisms specifically related to ejaculation is thus challenging. A neurobiological approach has been developed that is based on animal models and imaging techniques leading to major advances in the understanding of the neurophysiopharmacology of ejaculation and physiopathology of ejaculatory disorders. Description of CNS circuits (including the spinal generator of ejaculation) specifically controlling the ejaculatory response is a major milestone although many questions remain. Continuing exploration of the CNS control of ejaculation and identification of more selective pharmacological targets in the coming years will undoubtedly provide further insights and open new therapeutical avenues.

MALE REPRODUCTIVE PHYSIOLOGY

Male Puberty: Neuroendocrine Disruption of Reproduction

Julie Fudvoye, Jean-Pierre Bourguignon, and Anne-Simone Parent, University of Liège, Liège, Belgium; and University Hospital of Liège, Chênée, Belgium

Introduction: Peripheral Versus Central Effects of Endocrine Disrupting Chemicals on Reproduction

Reproductive functions involve the coordinated action of different central and peripheral structures including the hypothalamus, pituitary gland, gonads, uterus, vagina, breast, prostate, etc. Several studies have shown that exposure to endocrine disrupting chemicals (EDCs) is associated with reproductive disorders such as alteration of the timing of puberty, infertility, abnormal cyclicity, premature ovarian failure, testicular cancer or adverse pregnancy outcome (Gore et al., 2015). Some of those disorders have been shown to involve direct effects of EDCs on the gonads and other peripheral tissues. For instance, studies have reported that early exposure to bisphenol A altered fetal ovarian steroidogenic gene and microRNA expression in sheep (Veiga-Lopez et al., 2013; Rivera et al., 2011) and inhibited germ cell nest breakdown (Wang et al., 2014). Prenatal exposure to diethylstilbestrol (DES) leads to an increased expression of the homeobox A10 gene in the uterus through epigenetic mechanisms (Bromer et al., 2009). The testis is also directly targeted by EDCs during early human life, as indicated by intratesticular anomalies described in the testicular dysgenesis syndrome in human (Skakkebaek et al., 2001) which are very similar to testicular anomalies described in rodents after early exposure to phthalates (Sharpe et al., 1995). Central endocrine disruption initially received relatively less attention but increasing evidence during the past decade has shown that the neuroendocrine system is also targeted by EDCs (Gore, 2001; Bourguignon et al., 2010; Frye et al., 2012). This chapter will summarize the data illustrating the effects of EDCs on sexual differentiation of the brain as well as the hypothalamic control of puberty and reproduction.

Neuroendocrine Disruption of Sexual Differentiation of the Brain

Sex steroids such as estradiol or testosterone organize the sexual differentiation of the brain during critical developmental windows of development (Schwarz and McCarthy, 2008; Gore, 2008). This early organization at the hypothalamic level allows the coordination of sex appropriate reproductive physiology and sexual behavior. Sexual differentiation of the brain is mostly dependent on the action of fetal and maternal hormones on steroid hormone receptors, but others factors participate to the establishment of the sex differences. The aromatization of testosterone into estradiol by the enzyme p450 aromatase (present in specific brain regions during critical periods of perinatal development) is one of the mechanisms whereby testosterone acts to organize and sexually differentiate brain structures and chemistry in males (Roselli et al., 2009). Alpha fetoprotein is another factor involved in the sexual differentiation of the brain. This circulating protein is produced by the fetal liver and binds estrogens with high affinity. In addition to its known neuroprotective role, it specifically delivers estrogens to target brain cells to ensure female differentiation as described in rodents (Bakker and Baum, 2008). Although most of the sex differences in the brain are established during the prenatal and neonatal periods, it appears that pubertal hormones also contribute to the addition of new cells in the sexually dimorphic regions (Ahmed et al., 2008).

Two hypothalamic regions play a crucial role in the regulation of sexually dimorphic reproductive physiology: the anteroventral periventricular hypothalamic nucleus (AVPV) and the sexually dimorphic nucleus of the preoptic area (SDN-POA). The AVPV volume is sexually dimorphic: the region has been described as larger in female than in male rats. Testicular androgens, after aromatization into estrogens, appear to be responsible for this defeminisation/masculinization of the AVPV (Wright et al., 2010). AVPV neurons project onto and directly stimulate GnRH neurons in the preoptic area. In rodents, AVPV plays a well-established role in the control of the preovulatory LH surge (Wiegand et al., 1982; Ronnekleiv and Kelly, 1986). The SDN-POA is approximately fivefold larger in male than in female rats (Gorski et al., 1978, 1980). The volume of the SDN-POA is increased by estradiol aromatized from testicular androgens perinatally. It is thought to play a role in male reproductive behavior and mate choice (Rhees et al., 1999).

Because those nuclei express nuclear hormone receptors (Estrogen receptor alpha, Estrogen receptor beta, androgen receptor and progesterone receptor) (Chakraborty et al., 2003; Orikasa et al., 2002; Mann and Babb, 2005; Simerly et al., 1990; McAbee and DonCarlos, 1999; Quadros et al., 2002, 2007), they are potential direct targets of endocrine disrupting chemicals. Initial studies illustrated the effects of early exposure to phytoestrogens on sexually dimorphic nuclei in the hypothalamus. Phytoestrogens are naturally occurring plant compounds structurally or functionally similar to oestrogens. Isoflavones are the most hormonally active and most characterized phyto-oestrogens. They are found in soy beans but also in berries, wine, grain, nuts and soya-fortified foods (Kurzer and Xu, 1997). Most isoflavones bind nuclear estrogen receptors (ER) and act as partial agonists. They appear to have a higher affinity for estrogen receptor beta (ER β) (Kuiper et al., 1998) which could explain varying activity depending on the tissue

since ER β expression varies across cell types and is sexually dimorphic (Cao and Patisaul, 2011, 2013). Some isoflavones such as genistein have been shown to bind to GPR30 (Thomas and Dong, 2006). Recent data suggests that isoflavones can also alter DNA and histone methyltransferases as well as other modifiers of chromatin structure (Shanle and Xu, 2011; Li and Tollefsbol, 2010).

While not always in accordance, several studies have reported an effect of isoflavones which is consistent with an estrogenic effect with an increased volume of the POA in males. For instance, genistein administered prenatally until adulthood leads to an increased volume of the POA in exposed males but not females (Scallet et al., 2004). When the exposure is shorter, this increase is not observed or not maintained (Lewis et al., 2003).

Neonatal exposure to genistein increased tyrosine hydroxylase immunoreactivity in the male anteroventral periventricular nucleus (Patisaul et al., 2006, 2007), indicating that genistein leads to a demasculinization of the AVPV through interference with endogenous estrogens. Genistein has also been shown to decrease kisspeptin fiber density in the female anteroventral periventricular nucleus and arcuate nucleus (Losa et al., 2011).

Synthetic endocrine disrupting chemicals have been shown to affect sexual differentiation of the brain as well. Rubin et al. (2006) have shown that perinatal exposure to low doses of bisphenol A (BPA) reduced the sex differences in the population of tyrosine hydroxylase (TH) neurons in the AVPV, primarily through a decline in the number of labeled neurons in females. Another study from McCaffrey et al. showed a defeminization of the female AVPV (evaluated through a decrease of TH positive cell numbers) after perinatal exposure to a wide range of BPA doses (McCaffrey et al., 2013). Evidence of a demasculinization of the male SDN-POA (reduced volume as labeled by calbindin) was also observed after such exposure (McCaffrey et al., 2013). The volume of the sexually dimorphic nucleus of the preoptic area is larger in males exposed perinatally to low doses of BPA but not in female, suggesting a sex specific effect of BPA exposure on SDN-POA volume (He et al., 2012). However, a study from Kwon et al. has yielded discordant results since perinatal administration of BPA did not produce detectable effects on the SDN-POA volume (Kwon et al., 2000). Differences among results may be due to differences in the age of analyses, the timing of exposure, the route of exposure or the chosen doses of EDCs.

Neuroendocrine Disruption of Pubertal Timing

Secular Trend in Age at Puberty and Environment

Puberty is a life period characterized by the maturation of the hypothalamic-pituitary-gonadal axis. It involves both physiological and behavioral changes that ultimately lead to the achievement of reproductive capacity. Puberty results from the activation of a complex neuroendocrine machinery which leads to an increase in frequency and amplitude of gonadotropin-releasing hormone (GnRH) secretion in the hypothalamus (Herbison, 2016).

A reduction in menarcheal age has been reported between 1850 and 1960 in Scandinavian countries (Tanner, 1962) and further in many European countries and USA (reviewed in Parent et al., 2003, 2015). These observations were thought to be the result of the improvement in health and nutritional status with the changes in socio-economical conditions. After a constant advance between 1850 and 1960, it appears that, in several countries with relatively stable and uniform condition of life, menarcheal age has shown only minor progression during the past decades while breast development seems to still be advancing (Parent et al., 2015). Some studies have identified a secular trend towards early onset of puberty, irrespective of the level of BMI (Aksglaede et al., 2009), suggesting the involvement of other environmental influences, among which endocrine disruptors chemicals. Detailed analysis reveals that the pattern of age distribution is affected both in boys and girls. This justifies a revision of the belief according to which current changes correspond to an advancement of pubertal timing in females. Current variations in pubertal timing actually involve a trend towards earliness for initial pubertal stages and towards lateness for final pubertal stages. This data suggests a role for environmental influences including nutrition, stress and endocrine disruptors. This hypothesis is supported by some observations of association between early exposure to endocrine disrupting chemicals or other environmental factors and the age at onset of puberty as well as rodent data which will be described below.

Challenges in Demonstrating the Endocrine Disruption of Puberty Timing

Before discussing the available data linking exposure to EDCs and neuroendocrine disruption of pubertal timing, it is important to be aware of some challenges that we face in this area.

A growing body of evidence demonstrates that fetal and early postnatal life is a critical period of sensitivity to the effects of EDCs (Gore et al., 2015; Fudvoye et al., 2014). The capacity of environmental factors to shape the neuroendocrine system is thought to be maximal during fetal and early postnatal life and possibly less important when approaching the time of onset of puberty (Parent et al., 2015). However, most studies on the role of environmental factors in triggering onset of puberty focused on the period immediately preceding puberty (Parent et al., 2015). The current recommendations of the Organization of Economic Co-operation and Development (OECD) for testing effects of EDCs on rodent female puberty, define postnatal days 22–42 as the validated exposure period with timing of vaginal opening and increase in uterine weight as evidence of puberty. Those guidelines ignore the earlier period before 25 days that is critical for neuroendocrine maturation. The effects of environmental stressors on pubertal timing depend on the period of occurrence or exposure. For instance, prepubertal underfeeding may lead to delayed puberty (Biro et al., 2005; Dunger et al., 2006; Ong et al., 2004, 2006; Cheng et al., 2012; Himes, 2006; Roa and Tena-Sempere, 2010) whereas intrauterine growth restriction is associated with early puberty (Ibáñez et al., 2006, 2011). Likewise, psychosocial stress shortly

before or during puberty may cause delayed menarche or amenorrhea (van Noord and Kaaks, 1991; Tahirović, 1998) whereas advancement of puberty has been described in girls who had experienced such stress in early postnatal life or infancy (Moffitt et al., 1992; Wierson et al., 1993). Those data are consistent with the concept that environmental clues affect pubertal timing differently depending on the life period when they come into action. In the early phase of organization of adaptive mechanisms, adverse conditions can be interpreted centrally as a risk for species survival and are translated into need of early reproductive fitness. Reversely, in a period closer to puberty, similar adverse conditions can be interpreted as a risk for quality and outcome of pregnancy and are translated into a need for delayed reproductive fitness.

Another challenge comes from observations that are inconsistent with the classical toxicology perspective according to which there will be no effect of a chemical below a threshold of exposure. This principle implies that the dose-response relationship is linear. However, hormones have complex concentration-response patterns which lay the foundation for dose-response characteristics exhibited by EDCs (Gore et al., 2015). We have showed that neonatal exposure to BPA for 2 weeks leads to a delayed maturation of GnRH secretion after a low environmentally relevant dose and advanced maturation after exposure to a higher dose (Franssen et al., 2016). Opposing effects on male rat puberty have also been observed after exposure to lower or higher doses of phthalates (Ge et al., 2007; Saillenfait et al., 2008). In addition, low-dose mixtures, consistent with human exposure, can have effects not conforming to simple additive models (Kortenkamp, 2008; Christiansen et al., 2012). However, most animal and human studies so far have focused on one or a single group of EDCs.

EDCs exposure, by modifying the hormonal environment, can affect pubertal timing either through central mechanisms, acting at different levels of the hypothalamic-pituitary system or through interaction with the peripheral target tissues such as the breast, uterus, testis or ovaries. Peripheral mechanisms can coexist with central mechanisms or secondarily facilitate them. Such a concept is supported by the dissociation between advancement in age at onset of breast development in Denmark, the Netherlands and Belgium without parallel change in menarcheal age (Parent et al., 2015). A single pubertal event can be influenced by different endocrine pathways. For instance breast development can be due to ovarian estrogen secretion under the stimulation by pituitary gonadotropins and/or estrogenic effects of EDCs independently of hypothalamic-pituitary maturation. Moreover, EDCs can interfere with the physiological inhibitory feedback mechanisms of sex steroids at the hypothalamic-pituitary level while they can also stimulate neuroendocrine maturation of GnRH secretion (Rasier et al., 2006).

Disruption of the Hypothalamic Control of Puberty

Several animal studies have reported alterations of pubertal timing after exposure to EDCs. Some models allowed the identification of neuroendocrine mechanisms leading to such effects.

In females, the effects on EDCs on the timing of vaginal opening depend on the period of exposure (Parent et al., 2015). When the animals are exposed to BPA during pregnancy only, age at vaginal opening is either not affected (Tinwell et al., 2002; Murray et al., 2007) or early (Honma et al., 2002; Nikaido et al., 2004; Howdeshell et al., 1999). When exposure takes place between birth and 15 days of age, age at vaginal opening is either not affected (Adewale et al., 2009; Losa-Ward et al., 2012; Nagao et al., 1999; Yu et al., 2010) or early (Adewale et al., 2009; Losa-Ward et al., 2012; Fernández et al., 2009; Nah et al., 2011). A dose of 50 µg/kg causes advancement of puberty while 50 mg/kg has no effect, indicating a nonlinear dose-response relationship (Adewale et al., 2009; Losa-Ward et al., 2012). We also showed that a very low doses of 25 ng/kg/day from postnatal day 1 to 15 delayed maturation of GnRH secretion while a high dose of 5 mg/kg/day led to an accelerated maturation (Franssen et al., 2016). Taken as a whole, those studies show that BPA effects depend markedly on the window of exposure and the dose, with possible nonlinear dose-response relationship. Several studies have provided evidence of neuroendocrine changes after early exposure to BPA in the female rat. These will be discussed further in the mechanistic chapter below. Most studies investigating the consequences of neonatal exposure to genistein led to equivocal conclusions since age at vaginal opening was either normal with no dose-related effect (Nagao et al., 2001; Jefferson et al., 2005; Kouki et al., 2003) or early and dose- or duration-dependent (Lewis et al., 2003; Kouki et al., 2003) or even late and dose-dependent (Jefferson et al., 2009). Using phthalates, the period of exposure appears crucial since prenatal exposure accounts for late vaginal opening (Salazar et al., 2004) whereas postnatal exposure is associated with normal timing (Gray et al., 2006; Moral et al., 2007) or early vaginal opening irrespective of the dose (Hu et al., 2013; Ma et al., 2006). Polybrominated EDCs appear to cause either no change or delay in vaginal opening depending on the dose and irrespective of the period of exposure (Stoker et al., 2004; Lilienthal et al., 2006; Ceccatelli et al., 2006).

In male rodents, balano-preputial separation is commonly used as a marker of puberty. With the exception of early balano-preputial separation after exposure to phthalates (Ge et al., 2007; Saillenfait et al., 2008), EDCs appear to cause either no effect or a delay of sexual maturation in the male rodent. BPA does not show any effect whatever the dose and the window of exposure (Tinwell et al., 2002; Nagao et al., 1999; Tan et al., 2003; Ashby and Lefevre, 2000; Kato et al., 2006). Similarly, using a very low dose of BPA neonatally for 5 days, we did not see any effect of exposure on balano-preputial separation. However, when pulsatile GnRH secretion from hypothalamic explants is studied at 25 days in such exposed animals, GnRH pulse frequency is reduced, indicating a delayed maturation of GnRH secretion caused by BPA neonatally. This indicates that GnRH secretion could be extremely sensitive to disruption without being sufficient or lasting sufficiently to account for phenotypic changes. When similar doses of different EDCs are used at different periods of exposure in the male rodent, they are found to be effective in delaying puberty after postnatal (after weaning) exposure as opposed to no effects after prenatal exposure. Such findings are obtained using dichlorodiphenylchloroethylene (DDE), vinclozolin (Warner et al., 2004) or diethylstilbestrol (DES) (Warner et al., 2004; Mol et al., 2002) suggesting that the fetus is less sensitive than the juvenile animal. The newborn rat can also be more sensitive than the fetus as found after

exposure to DES (Warner et al., 2004). Such a conclusion was also drawn in a review of several studies on BPA effects in the female rat since gestational exposure has no effect on age at vaginal opening whereas neonatal exposure is followed by early puberty (Guo et al., 2004). Importantly, both periods of exposure fall into the so-called “programming window” indicating that, even within this particular period, there may be differences in sensitivity to endocrine disruption. The dose of EDC however plays a critical role since, when investigated at a given period of life, higher doses appear to be more effective such as shown after prenatal exposure for DDE (Leijs et al., 2008) and phthalates (Denham et al., 2005; Den Hond et al., 2002), or after lactational exposure for DDE, vinclozolin or DES (Warner et al., 2004) or following exposure after weaning for DDE (Grandjean et al., 2012; Warner et al., 2004), vinclozolin (Warner et al., 2004; Adgent et al., 2012), DES (Warner et al., 2004; Kim et al., 2011), phthalates (Deng et al., 2012; Strom et al., 2001) and polybrominated diphenyl ethers (PBDE) (Giampietro et al., 2004). It is noteworthy that in two studies using phthalates, opposing effects are observed since lower doses are associated with early puberty and higher doses with delay (Deng et al., 2012; Denham et al., 2005). Interestingly enough, we have reported similar opposing effects using DES neonatally in the female rat (Fernandez-Rhodes et al., 2013).

Neuroendocrine Disruption of Ovulation

Ovulation is under the control of GnRH secretion which is tightly regulated by the positive and negative feedbacks of gonadal steroids. In both males and females, GnRH secretion is suppressed by the negative feedback taking place at the level of the arcuate nucleus. The positive feedback of estrogens is mediated by the AVPV and potentiates the surge in GnRH and subsequently luteinizing hormone (LH) that precedes ovulation. In rodents, the sexual differentiation of this positive feedback takes place during the perinatal period and is particularly sensitive to disruption by hormones and EDCs. It has been shown that the administration of testosterone or estradiol benzoate during the neonatal period can alter the positive feedback by estradiol (Padmanabhan and Veiga-Lopez, 2014). Such data suggests that early exposure to EDCs could alter the programming of the preovulatory LH surge. In addition, exposure to EDCs during adulthood could alter the central control of ovulation. This article will summarize the effects of neonatal or adult exposure to EDCs on the hypothalamic control of ovulation. As discussed above for puberty, it is sometimes difficult to differentiate the effects of EDCs on the central versus the ovarian control of ovulation. Some animal models can help to shed light upon such aspects.

The sheep offers a good model for studying the effects of EDCs on the neuroendocrine control of ovulation thanks to the availability of noninvasive approaches to monitor follicular dynamics as well as surgical approaches to obtain hypophyseal portal blood (Padmanabhan and Veiga-Lopez, 2014). Prenatal exposure of female sheep to excess androgens has been shown to lead to adult reproductive disorders with LH excess, multifollicular ovarian morphology and corpus luteus dysfunction. Such early exposure to testosterone disrupted the estradiol negative feedback (Wood and Foster, 1998; Sharma et al., 2002), estradiol positive feedback (Wood and Foster, 1998; Sharma et al., 2002) and progesterone negative feedback (Robinson et al., 1999). Neonatal exposure to BPA leads to reproductive disorders similar to those found in testosterone exposed sheep with LH excess and severely dampened preovulatory LH surge (Savabieasfahani et al., 2006).

Neonatal exposure to BPA in rodents has been shown to disrupt pubertal timing but also leads to premature anestrus and ovarian anomalies. As described for the sheep, these anomalies could result from disrupted organization at the level of the hypothalamus/pituitary or at the level of the ovaries. Adewale et al. have shown that alterations of estrus cycle caused by a relatively low dose of BPA was not accompanied by a reduction of the number of GnRH neurons expressing the immediate early gene *c-fos* suggesting that steroid-positive feedback was not defeminized by BPA. However, this study did not rule out the possibility that other regulation of the GnRH neurons could have been altered (Adewale et al., 2009). Other studies suggest that neonatal exposure to BPA decreased basal and GnRH induced LH secretion and increased GnRH pulsatility in adult rats, suggesting a permanent effect on GnRH pulsatility and pituitary signaling (Fernández et al., 2009). There is relatively less information on the neuroendocrine disruption of ovulation caused by EDCs other than BPA. Exposure to TCDD (2,3,7,8-tetrachlorodibenzo-para-dioxin) has been associated with abnormal ovulation and premature ovarian failure (Gregoraszczyk and Ptak, 2013). While some studies showed that TCDD disrupted estradiol secretion in human granulosa cells (Baldridge et al., 2015), others have reported alteration of the hypothalamic-pituitary axis. Takeda et al. (2014) have showed that exposure of pregnant rats to TCDD led to decreased expression of gonadotropins in pups and LH and FSH levels appeared to be decreased in virgin female mice (Huang et al., 2011). Tributyltin chloride is used as a biocide in antifouling paints which exposure has been associated with obesity. It has recently been shown to alter estrus cyclicity and cause decreased surge LH levels and GnRH expression (Sena et al., 2017). Very few data is available regarding the effects of phthalates on estrus cyclicity and ovulation. One study showed that exposure to DEHP during adult life led to increased duration of estrus in mice (Hannon et al., 2014).

Mechanisms of EDCs Effects on the Overall Neuroendocrine Control of the Reproductive System

The hypothalamic-pituitary-gonadal axis is responsible for the development of puberty and acquisition of the reproductive function. A subset of neurons in the anterior hypothalamus secrete gonadotropin-releasing hormone (GnRH) which, through its pattern of release, controls all aspects of reproductive function throughout life. The secretory activity of GnRH neurons depends on trans-synaptic and glial inputs mediated by neurotransmitters and cell-cell signaling molecules. New methods have provided more

information regarding the dynamic coordination of network contributing to the central control of the pubertal process and reproduction (Ojeda and Lomniczi, 2014). When studying the central mechanisms potentially involved in the neuroendocrine disruption of puberty or ovulation, GnRH neurons appear to be a potential target of exposure to endocrine disruptors. Using a murine model of neonatal exposure to dichlorodiphenyltrichloroethane (DDT), our team has confirmed the involvement of neuroendocrine disruption in the alteration of pubertal timing. Pulsatile GnRH secretion was accelerated after early exposure to DDT and this effect was followed by early sexual maturation (Rasier et al., 2007). Further studies have indicated that such effects involve the estrogen receptor, the orphan dioxin (AhR, arylhydrocarbon) receptor and a subtype of glutamate receptor (Rasier et al., 2008). Another study of our group showed that exposure to DES (10 µg/kg/day) during the first 5 days of life was associated with early vaginal opening while a dose of 1 µg/kg/day was associated with delayed vaginal opening and delayed developmental increase in GnRH pulse frequency (Franssen et al., 2014). DES is a potent synthetic estrogen which was prescribed to prevent miscarriages during the 1950s and 1960s. Its prescription is now because of the increased risk of vaginal cancer after in utero exposure. DES is still used as a paradigmatic EDC in animal models. Our observations counteract the classical hypothesis that EDCs cause sexual precocity. Although precocity is indeed observed in several studies and possibly reflects both peripheral and central mechanisms, delayed female puberty after neonatal exposure to a potent estrogenic EDC is a new finding that is likely to be of neuroendocrine origin. In addition, it appears that prenatal food restriction could have additive effects to neonatal DES exposure on the neuroendocrine effects of leptin. When females were exposed in utero to prenatal food restriction and postnatally to DES, the stimulatory effect of leptin on GnRH secretion in vitro was completely blunted (Franssen et al., 2014). This reinforces the demonstration of a neuroendocrine disruption of GnRH secretion and illustrates the potential additive effects of different environmental stressors.

Other studies have shown effects of EDCs on GnRH secretion. Fernandez et al. demonstrated an increase of GnRH pulsatility in infantile rats after neonatal exposure to BPA (Fernández et al., 2009). Interestingly, GnRH pulsatility remained disrupted in adult rats neonatally exposed to BPA (Fernández et al., 2009). Losa-Ward et al. (2012) have reported morphological alteration of RFamide-related peptide-3 (RFRP3) neurons known to inhibit GnRH neuron activity after neonatal exposure to BPA. They showed reduced RFRP3 perikaria, fiber density and contacts on GnRH neurons, suggesting that BPA-induced premature puberty could result from decreased inhibition of GnRH neurons. GnRH neurons response to steroid-positive feedback, however, was not affected by neonatal exposure to BPA in the study from Adewale et al. (2009). More recently, our group has reported that the developmental increase in frequency of GnRH release at the time of puberty is delayed in female rats exposed neonatally to a low dose of BPA (25 ng/kg/day). Interestingly, the effects were opposite with a high dose of BPA (5 mg/kg/day). The mechanism involved respectively increased or reduced tone of γ -aminobutyric acidergic (GABAergic) neurotransmission which is known to play an inhibitory control on GnRH secretion (Franssen et al., 2016).

Neuroendocrine disruption of reproduction can act through interference with the production or the action of brain neuropeptides which regulate GnRH secretion. Kisspeptin, encoded by the KISS1 gene, is known to stimulate GnRH secretion and plays a crucial role in the onset of puberty (Seminara et al., 2003; de Roux et al., 2003). Navarro et al. have shown a reduction in hypothalamic expression of KISS1 mRNA at puberty after neonatal exposure to a high dose of BPA as it was observed after exposure to estradiol benzoate (Navarro et al., 2009). Similarly, Patisaul et al. found a reduction in kisspeptin immunoreactivity (estimated in term of fibers density) in the arcuate nucleus in adult female rats (Patisaul et al., 2009) after neonatal exposure. Regarding the earlier vaginal opening that occurs after exposure to a high dose of BPA (Franssen et al., 2016), those observations were unexpected since Kiss1 is considered as a major gatekeeper of puberty onset. The reduction in kisspeptin expression could then be part of a reactive mechanism to BPA exposure. Similarly, a study performed in the sheep showed a decrease of Kiss1 mRNA levels at the rostral, mid and caudal regions of the hypothalamus in foetus exposed in utero to a complex mixture of EDCs (Bellingham et al., 2009). Such effects were not observed after adult exposure, supporting the hypothesis that the period of exposure is critical for such regulatory processes. Xi et al. (2011) showed that perinatal exposure to a high dose of BPA resulted in the up-regulation of the expression levels of KISS-1 and GnRH in both male and female pups. This observation was not replicated after postnatal exposure to BPA, highlighting once again the critical perinatal period for BPA affecting reproductive neural circuits in hypothalamus (Xi et al., 2011). Acute infusion of BPA in the stalk-median eminence of mid to late pubertal female rhesus monkeys led to a suppression of GnRH and kisspeptin secretion for the highest doses while lower doses did not have any apparent effects (Kurian et al., 2015).

GnRH neurons themselves express ER β but also G protein coupled receptor 30 (GPR30) and estrogen-related receptor γ , all potential receptors for endocrine disrupting chemicals. Thus GnRH neurons could be directly targeted by EDCs. A recent study has shown that BPA significantly decreased calcium activity in GnRH neurons in explants. Blockade of GABAergic and glutamatergic input did not abrogate the inhibitory effect of BPA, suggesting a direct effect of BPA on GnRH neurons (Klenke et al., 2016). Other studies in fish suggest that early exposure to BPA ou bisphenol S could increase the number of GnRH3 neurons during development which suggests a broader effect of BPA and BPS on neurodevelopment (Qiu et al., 2016).

Conclusion and Perspectives

The hypothalamus provides a unique site for finely tuned integration of endogenous and environmental factors influencing the control of puberty and reproduction. While initial studies focused on the effects of EDCs on peripheral organs, recent data have shown that the hypothalamic-pituitary control of reproduction can be targeted by environmental pollutants. While such effects are extremely difficult to study in humans, animal models play a crucial role in deciphering the neuroendocrine mechanisms of

action of such compounds. Neuroendocrine effects of EDCs can be opposing and involve different mechanisms depending on the dose or whether they take place early, during fetal and neonatal life or late during prepubertal life.

These last few years, the knowledge of molecular and genetic mechanisms controlling the pubertal process has accelerated considerably. Puberty results from coordinated changes in a multiplicity of genes organized into functional networks. Recent evidence suggests that a dual mechanism of epigenetic regulation affecting the transcriptional activity of neurons involved in stimulating GnRH release plays a fundamental role in the timing of puberty (Ojeda and Lomniczi, 2014; Lomniczi et al., 2015). In addition, a multilayered microRNA-operated switch appears to be involved in the increase in GnRH expression during the prepubertal period (Messina et al., 2016). Epigenetic repression and activation of gene transcription might be a mechanism by which environmental factors affect pubertal development and reproduction. Because EDCs have been recently shown to alter DNA methylation, histone modifications and microRNA expression (Gore et al., 2015), further studies will be needed in order to explore the involvement of such mechanisms in the neuroendocrine disruption of reproduction.

Introduction

Fertility varies considerably between males. Thus, assessments of male fertility are necessary for different reasons, and in different situations, and this is generally not an easy task. Evaluation of male reproductive condition may rely on assessments of fertility or fecundity rates, lifetime reproductive success, or the examination of behavioral or physiological traits, including semen quality. These different approaches involve each potential difficulties. Firstly, fertility or reproductive success requires assignment of paternity in natural populations, or the separation of male and female factors in domestic species or humans. Secondly, in the absence of efficient or reliable methods to quantify reproductive success, it is necessary to rely on physiological traits, such as semen parameters; this, however, has limitations because of our incomplete knowledge of how different sperm or seminal plasma traits determine fertility. Despite these limitations, diagnosis and prognosis of male fertility is now of major concern for humans and animals worldwide. This is emphasized by recent studies in human males pointing towards a decline in sperm quality and an increase in several male reproductive problems, such as testicular cancer, cryptorchidism, low testosterone levels, and an accompanying rise in the demands for assisted reproductive techniques.

Differences in male fertility in natural populations of wildlife are vast. It was once considered that, because males are under strong selection pressure, they would have consistently high fertility (Gomendio et al., 2007). Furthermore, it was assumed that males had an almost unlimited supply of gametes, and that producing spermatozoa was “cheap.” Hence, males would not suffer constraints in their fertility. This view can no longer be held because it is now known that males vary widely in their fertilization success, even if they have access to females and copulate. In addition, in species under different forms of threat, such as excessive hunting or reduction of habitats, which results in reductions in population size, there will be a higher prevalence of matings among related individuals. This situation would lead to an increase in inbreeding and loss of genetic diversity, followed by a decrease in fertility, which would negatively feedback on the population by further reducing its size, increased matings among relatives and, thus, give rise to an extinction vortex. There is ample evidence now that inbreeding results in a decrease in some male reproductive parameters, including a deterioration in semen traits, with increases in sperm abnormalities and sperm DNA damage (Roldan and Gomendio, 2009).

Among livestock, there has been a long-standing interest in fertility because of its direct link to production in domestic species. It is estimated that about 50% of breeding failure is associated to male infertility. Considering that approximately 70% of dairy cattle and about 90% of pig livestock are currently produced by artificial insemination, reduction in male fertility accounts for huge economic losses in the animal industry. Furthermore, there is sometimes a tendency to overuse specific males, because of their desirable traits (i.e., for genetic improvement), and this can potentially lead to decrease in genetic variability with negative consequences on reproduction and fertility. In companion animals, or animals used in sports, such as dogs or horses, there is a more individual approach to fertility, with conditions affecting fertility being examined and treated with a strategy similar to that used in human males. For some species, or breeds, there is also interest in artificial insemination and, therefore, the need to evaluate the reproductive potential of males, or semen samples, is also of interest.

In humans, there is also considerable variation in fertility. Human male fertility is of interest to demographers and epidemiologists although the approaches they use, and the emphasis on fertility and fecundity, seem to differ among them. Thus, demographers are interested in circumstances in which live births occur, with the aim of predicting population changes, whereas epidemiologists place emphasis on what may be regarded as fecundity (“fecundability”), which is based on determination of the time to pregnancy. There is now considerable overlap, and some interchange in terminology, between the two approaches taken to understand variation in human fertility. Thus, there is both interest in understanding variation in timing to pregnancy and the factors that may affect it and how this, in turn, affects changes in population.

In the European Union and Japan there is currently a persistently low total fertility rate, below the replacement level of 2.1 child per woman; in the United States, the fertility rate has also declined but there are differences between ethnic groups, with Caucasians having rates that are below replacement values (Skakkebaek et al., 2016). This has led to the prediction that there will be appreciable decreases in their populations in the immediate future. Part of this decline may be due to social issues and part could be related to fertility problems. What is, then, the prevalence of human infertility and what proportion of such infertility is due to male factors? This is a simple question but, unfortunately, not an easy one to answer. It is important because defining the extent of a disease is crucial to estimating its impact, assess health economic arguments, know prevalence in different populations, and decide what resources should be applied to study and to alleviate it (Barratt et al., 2017). Nevertheless, despite a long-standing interest in these issues, most of the aspects mentioned here are still little known. Infertility is generally defined as the failure of a couple to establish a pregnancy despite 12 or more months of unprotected intercourse. General estimates indicate that about 10%–15% of couples exhibit difficulties for conception, with half of them experiencing some form of male factor; in other words, about 5%–8% of all males of reproductive age exhibit subfertility or infertility. Recent surveys suggest that about 1 in 8 women and 1 in 10 men have experienced infertility. Figures could be higher because there is currently no method to identify men, as individuals, who may be infertile (Barratt et al., 2017). Much variation has been identified between studies estimating infertility due to methods, geographic variation, or populations. One approach generally used to assess male infertility is to examine semen parameters in

men in the general population. Many studies have done this and the information has also been used to try to identify changes in semen quality over time. The information may be valuable if the populations are well characterized and standardized methods are employed across studies. There are also limitations due to the fact that it is not possible to equate the results of semen analyses with male fertility, particularly if only few parameters are assessed.

It seems that male fertility is declining. Evidence from studies reporting semen quality over the years appears to support this claim. A recent major meta-analysis (Levine et al., 2017) has examined sperm concentration and total sperm count from a total of 185 studies, including 42,935 men, and covering the period 1973–2011. The slopes of sperm concentration and total sperm count were estimated as functions of sample collection year. Results of the study showed that sperm concentration declined significantly in the period 1973–2011 with an overall slope in adjusted meta-regression models of -0.64 million/mL/year, which was influenced by fertility and geographic group. Among unselected Western studies, the mean sperm concentration declined, on average, 1.4% per year with an overall decline of 52% during this period. Tendencies for total sperm counts were similar to those of sperm concentration, with a marked decline among unselected Western studies (-5.33 million/year), an average decline in mean total sperm count of 1.6% per year, and an overall decline of about 60%. This study therefore revealed a significant decrease in sperm counts during a period of about 40 years, driven by a 50%–60% decline among men unselected by fertility from North America, Europe, Australia and New Zealand. Research on the causes of this decline is required because of the major public health implications of these findings.

Variation in male fertility is evaluated taking into account the many factors that can affect it, including genetic abnormalities, diseases, environmental factors and, among human males, occupational hazards or differences in lifestyle (Skakkebaek et al., 2016). Among the genetic component that may affect human male fertility, there are chromosomal abnormalities (e.g., aneuploidies or translocations), microdeletions of the Y chromosome, or mutations (e.g., cystic fibrosis or mutations associated to sperm formation or function). A variety of diseases have been identified to affect male fertility, including a series of ill-defined entities such as infections, varicocele or iatrogenic causes. Several environmental chemicals, as well as substances present in the workplace, may also have an impact on fertility. A series of endocrine disruptors may be responsible for effects on testicular development, hormone levels and sperm quality, whereas a variety of heavy metals such as lead or pesticides may impact on semen. Finally, an array of lifestyle conditions, including obesity, smoking, alcohol or drug use, clothing or stress are also known to influence male fertility. Another factor which also influences male fertility is age and with the current protracted life expectancy in many countries, and opportunities for fatherhood later in life, it is also relevant to understand the impact of male age on sperm quality and sperm DNA integrity particularly with regards to potential mutations that can lead to genetic disease in offspring.

There are thresholds in semen quality below which fertility is compromised, and there is considerable interest in understanding reasons behind this fall in semen quality and male fertility. The purpose is twofold. Firstly, by understanding reasons underlying subfertility or infertility, to try and develop methods to diagnose causes that lower fertility. Secondly, by manipulation of gametes or semen, try to enhance methods for treatment, including the development of assisted reproductive techniques. In this second category, there is also considerable interest in developing methods to evaluate and, hopefully, predict fertility potential in species of commercial interest for which a variety of methods of assisted reproduction are being used. In this regards, species in which semen cryopreservation, artificial insemination, sex preselection or embryo production, are widely employed technologies, increases in male fertility (including the possibility of predicting male fertility or, perhaps, sperm fertility) is a goal that commands much interest.

Overall, there are several factors that can influence fertility but one that seems to be on the rise (and that generates increasing concern) in humans and animals relates to the influence of environmental chemicals (Lewis and Ford, 2012; Vested et al., 2014). There are many studies now that have called our attention to this issue and, although the evidence still seems somewhat controversial, there is sufficient information to suspect an adverse environmental effect on male reproduction. In humans, there are now clear data showing a decrease in sperm counts, and rises in the prevalence of cryptorchidism and testicular cancer. Since these problems cluster in certain geographical areas they are thought to have common origins and have thus been associated to endocrine perturbations in early life. These problems are not restricted to humans. Many studies on wildlife suggest an important effect of environmental chemicals on male reproduction and, similarly, environmental contaminants may affect livestock and companion animals. In a study carried out in dogs it was found that they also may be experiencing a decline in fertility (Lea et al., 2016). Dogs of different breeds that were systematically examined for sperm quality for over 25 years were found to have a decline in sperm motility during this period of time, together with an increase in cryptorchidism and a bias in sex ratio, with less males being born over this period. Environmental chemicals are suspected to be responsible for these changes since they were found in dog food and testes. These results suggest that there may be some direct effect of chemicals on sperm, similar to what has been suggested for humans. Therefore, it is important to devote efforts to clarify how these contaminants may negatively affect male fertility in a variety of species including humans.

Determinants of Male Fertility

Male fertility is not determined by semen or sperm traits alone. There are other factors (i.e., hormonal, immunological, genetic/chromosomal, behavioral) that are relevant besides semen quality, but these are somewhat more difficult to quantify or relate to male fertility. Thus, much effort has been placed on trying to understand the relation between semen traits and male fertility (De Jonge and Barratt, 2017). Semen evaluation has moved towards more objective ways of examining the different constituents

of the ejaculate, including sperm numbers, cell morphology, sperm dimensions, various sperm functions and the underlying mechanisms that lead to successful fertilization (Barratt et al., 2017). Nevertheless, under routine conditions, semen analysis relies on just a few traits so the objective of uncovering links between sperm traits and fertility has remained elusive. In addition, there are substantial differences in the focus of attention when one considers studies in domestic species and those in human males. The former have been the subject of intense selection, including fertility traits, whereas among the latter studies are mainly of infertile patients; therefore, there may be little variation at each end of the range, with limited possibilities for the identification of critical sperm traits that could explain diversity in fertility. Studies on wildlife or populations of domestic species not yet subjected to strong selection has allowed for the identification of semen traits that are important determinants of fertility. In natural populations in which male fertility varies between 20% and 80% it was found that some traits seem to be directly associated to fertilization success, such as the proportion of morphologically normal sperm, and sperm swimming velocity, which are thus key determinants of male fertility (Gomendio et al., 2007).

In studies in human donors and infertile patients, and also in males from domestic species, it has been shown that one single sperm parameter cannot generally be associated to the fertility of the male. Even when a series of basic traits such as sperm concentration, morphology or motility are taken into account, a multi-parametric analysis is more informative than just a single one. With this in mind, research has focused on the identification of relevant sperm parameters that, being important for sperm transport, survival and fertilization, could be used in combination in the design of better assays. One aspect that should be borne in mind is that an ejaculate exhibits considerable heterogeneity in its sperm traits. As a consequence, it has been realized that it may not be very informative to rely solely on average values for each trait but, rather, that subpopulations of spermatozoa should be identified and, subsequently, that the structure of these subpopulations in different males, or ejaculates, may render more useful information (Ramón et al., 2014). One additional point to bear in mind is that spermatozoa need to survive for a long time, either in the female tract, between ejaculation and the time of fertilization, with many changes taking place during this period of time, or during storage either by means of refrigeration or cryopreservation. Survival in the female tract and storage bring about modifications that may hamper the chances of fertilization. Tests of sperm function may take these aspects into account so, rather than making a single assessment of a battery of traits, assays should probably incorporate assessments at different time points and report kinetics rather than static values (Petrunkina and Harrison, 2013). The sections below will briefly summarize information on sperm parameters, and tests that may be used to assess them, taking some of these issues into consideration.

Sperm Traits and Use in Diagnostic Tests

We tend to distinguish semen traits that relate to quantity from those that are linked to quality of spermatozoa. Quantity refers to sperm numbers in the ejaculate, expressed either as sperm concentration or total sperm count (that is, number of sperm in the total volume of the ejaculate). Quality is used to refer to traits linked to morphology, integrity, cell viability or motility and functional ability. This so-called qualitative traits are quantified expressing the proportion of sperm cells in different categories, but giving numbers to certain attributes is difficult. There has been enormous efforts, particularly for human semen analysis, to develop standardized methods and quality assurance. Recommendations are available in the form of laboratory manuals for clinical andrology, as endorsed by the World Health Organization (Barratt et al., 2017).

There has been a long-standing interest in identifying criteria for what may be regarded as normal sperm morphology. In humans, which have very pleiomorphic sperm, a set of “strict” criteria has been presented and promoted to identify “normal” spermatozoa (Barratt et al., 2017). Morphology can be assessed under the microscope using a variety of staining techniques or under phase contrast, or with more recent technologies to immobilize spermatozoa to avoid artifacts due to sample processing. By using a series of fluorochromes, shapes of the sperm nucleus and acrosomal granule can be distinguished and characterized separately. Computer-assisted sperm morphometry analysis (CASMA or ASMA) has been developed to reduce the subjectivity of assessments; several systems are available, either commercially or as free software (Yániz et al., 2015). In order to obtain more detailed information, some simple equations for elongation, rugosity or regularity have been used to estimate sperm head shape from dimensions and areas, with a view to assessing head morphology in more detail. These equations have been incorporated into computer-aided sperm morphology analyses. More accurate approaches to sperm morphology have been proposed, including the use of Fourier shape analyses or geometric morphometrics, which may prove to be more informative. These may also be amenable to automation and incorporation into computer-aided systems in the future.

Motility evaluation has developed from a subjective assessment under the microscope to computer-assisted sperm analysis (CASA) with many systems now available either commercially or as free software (Amann and Waberski, 2014; Mortimer et al., 2015). These systems have improved due to developments in image capture from a microscope, increases in computational power and concomitant reduction in computer size and new software, although the basic concepts seem to have remained essentially unchanged. It is important to distinguish the ways in which “sperm motility” is used. On the one hand, motility may refer to the quantification of the proportion of cells moving, even discriminating different types of motility (e.g., proportion of progressive or non-progressive motility), based on either subjective or CASA-derived estimates. On the other hand, motility is assessed as “kinematics” with a series of parameters, or descriptors, used to characterize sperm movement, that is, sperm swimming, with further discrimination of parameters that describe swimming velocity and others that refer to swimming trajectory. These parameters can be quantified with CASA systems. Sperm kinematic parameters can be quantified and analyzed either as averages or as subpopulations identified via other algorithms available now for mouse and human spermatozoa. The latter serve to quantify

subpopulations of hyperactivated sperm cells. CASA systems have now expanded beyond their use in motility evaluation. Being a combination of image capture and computer image assessment, the concept of CASA now refers to a suite of parameters that can be evaluated with the same set up. Thus, by varying sample preparations, sample examination (e.g., under phase contrast, bright field or fluorescence) CASA systems now provide options to estimating sperm concentration, viability, morphometry/morphology, acrosome integrity, or sperm DNA integrity. These systems have therefore evolved into an instrument of image analyses that can serve to quantify in an objective manner a variety of traits in spermatozoa subjected to a number of tests.

Sperm DNA Damage and Role of Protamines

Spermatozoa have the very important function of carrying the paternal haploid nuclear genome to the oocyte. Tests of sperm DNA integrity and sperm nuclear protein have shown potential to discriminate infertile from fertile men or animals or to identify changes in sperm DNA taking place during sperm storage by cryopreservation. Thus, in addition to testing the ability of sperm to fertilize, it is also crucial to examine whether there are damages in the sperm genetic load because such damages, in addition to affecting the sperm's fertilizing ability, may negatively affect embryo or fetal survival, postnatal development, or because damages to sperm DNA may give rise to genetic diseases in the offspring. Thus, assessments of sperm DNA integrity could provide additional information of sperm quality not identified by evaluation of other sperm parameters. Damage to sperm DNA can be examined by a variety of methods such as the sperm chromatin structure assay (SCSA), terminal deoxynucleotidyl transferase nick end labeling (TUNEL), the sperm chromatin dispersion (SCD) assay, or the Comet assay. Each assay measures different aspects of sperm DNA damage.

Sperm DNA damage is prevalent among infertile men and is known to influence natural reproduction. On the other hand, the impact of sperm DNA damage on the outcome of assisted reproduction is still controversial and this may be due to the variety of methods used. A recent meta-analysis ([Simon et al., 2017](#)) examined possible relations between human sperm DNA damage (assessed by SCSA, TUNEL, SCD or Comet assay) and clinical pregnancy after in vitro fertilization (IVF) and/or intracytoplasmic sperm injection (ICSI) treatments. From 56 studies including a total of 8068 treatment cycles of IVF, ICSI, and mixed IVF plus ICSI, the results indicated that sperm DNA damage affects clinical pregnancy following assisted conception. Interestingly, there were differences regarding the different methods used to assess sperm DNA damage, with methods that measure DNA integrity directly (TUNEL and Comet) revealing more consistent associations with pregnancy outcomes than the methods that indirectly measure DNA integrity (SCSA and SCD). Nonetheless, there seems to be sufficient evidence to suggest that sperm DNA damage has a negative effect on pregnancy.

In endangered species a relationship between sperm DNA damage and sperm abnormalities, which were related to inbreeding levels, was observed and, more importantly, sperm DNA damage was found to be associated to neonatal offspring survival ([Ruiz-López et al., 2010](#)). These results have important implications for conservation efforts and underscore again the negative impact of inbreeding in endangered species.

Storage of sperm by cryopreservation may have detrimental effects on sperm DNA integrity. Several studies in man, domestic species and wildlife have shown that sperm experience DNA damage when exposed to subzero conditions and that additions to semen extenders have different ability to protect sperm from such damage. Cooling and freezing rates also influence the integrity of sperm DNA and differences between individuals in their ability to survive cryopreservation are reflected also in the integrity of sperm DNA.

The realization that sperm may carry damaged DNA, and that this associates with pregnancy loss, or disease in the offspring, has led to an interest in the etiology of DNA damage. Several studies suggest that protamine deficiency is related to DNA damage and male fertility. In primates (including man), most rodents and a few other species there are two protamines (protamine 1 and protamine 2) and the ratio between them is important for sperm head (chromatin) compaction and the protection of DNA. There seems to be a constant protamine ratio for each species, although ratios vary between species. A recent review and analysis examined data from the literature on the relationship between the ratio of protamine 1 and protamine 2 with male fertility and the association of protamine deficiency with sperm DNA damage measured using different methods ([Ni et al., 2016](#)). A significantly higher protamine ratio was identified in subfertile men when compared with controls; both protamine mRNA ratio and protein ratio were found to be significantly increased in subfertile patients. The association between protamine deficiency and DNA damage exhibited a significant combined overall correlation coefficient. Interestingly, the level of "protamination" (i.e., protamine deficiency) measured by chromomycin A3 staining was significantly associated with sperm DNA damage whereas the protamine mRNA or protein ratio was not. These results should be interpreted with caution because of the diversity of methods used to assess DNA damage but, nevertheless, from this meta-analysis it seems that protamine ratio may be a suitable biomarker for the assessment of sperm quality whereas protamine deficiency (protamination) is closely related with sperm DNA damage.

Functional Sperm Tests

Taking into account the prevalence of human male infertility, the need to ensure high quality semen samples for domestic species of economic importance, and the interest in preserving gametes from endangered animals, it is important to have reliable methods for laboratory evaluation of semen traits. The predictive value of semen analysis is thus paramount. Here, it is important to distinguish the value of semen analysis as a method to assess the fertility of a male, from the capacity to predict the fertilizing potential of a given semen sample to be used in assisted reproductive techniques. When considering the predictive value of semen analysis for

reproductive outcome, the question is which is the best approach to analyzing sperm traits. Thus, is the evaluation of one ejaculate better than two or more ejaculates for referral to infertility investigation, is a combination of several parameters better than just a single parameter, or is a set of parameters representing a wide range of basic and functional traits better than a limited set of basic parameters?

For cases of human male infertility, it seems that assessment of one ejaculate may be adequate for referral to infertility investigation and treatment, although there is controversy regarding this conclusion because there may be a subgroup of men in the intermediate range requiring repeated semen analysis. On the other hand, a combination of basic parameters seems more predictive than the assessment of just one trait. In any case, it is now clear that the use of a simple set of parameters is insufficient, and calls to expand the array of traits to be examined argue for the inclusion of several tests that would examine sperm function (Barratt et al., 2017). In domestic species, narrow differences in sperm fertility may have enormous economic impact, so there is considerable interest in identifying and implementing a battery of tests that better allow for comprehensive assessment of the effect of storage conditions and fertilizing ability. Thus, in this framework, many studies have proposed and tested a variety of assays that examine the ability of sperm to survive under a variety of conditions, and assays that test for the capacity of sperm to respond to signals that prepare them for fertilization during the processes of capacitation, acrosomal exocytosis and interaction with the oocyte. Currently, a suite of parameters and possible tests can be used for these purposes, mainly in the research laboratory, but, nonetheless, more research is required to better understand processes of formation, maturation and preparation for fertilization, whose knowledge may result in more reliable tests that could be used in the future on a routine basis.

Semen analyses (for human males but also in general for other species) usually do not include functional tests that could identify cases of infertility (or predict fertilizing potential). Semen analysis is generally restricted to a set of basic semen traits including sperm concentration, morphology, or motility. Sperm cells experience a series of changes before fertilization. They need to undergo capacitation, acrosomal exocytosis (the so-called acrosome reaction), develop hyperactivated motility, traverse the oocyte coats and fuse with oocyte's membrane. If sperm are used in assisted reproduction, either in animals of economic interest or infertile patients, there is a need to ensure that spermatozoa will experience these changes with an appropriate timing because, otherwise, the success of fertilization would be compromised. These changes take place in the female tract but can be mimicked in the laboratory and efforts have thus been directed to understand the underlying mechanisms of these changes and, furthermore, design tests that can reliably and affordably assess these processes and the underlying mechanisms. Many efforts to design appropriate tests deal mainly with capacitation and acrosomal exocytosis, so a brief summary will be presented below.

Functional Tests for Capacitation

Capacitation is an essential process that involves a series of cellular and molecular changes and is required for acrosomal exocytosis and interaction with the oocyte. The process is still ill-defined and the understanding of what it entails and when it is completed varies between research laboratories. The main difficulties lie in the definition (and identification) of what represents a capacitated sperm. Capacitation has been examined using a series of tools and criteria, and some assays have been devised to examine the ability of spermatozoa to undergo this process.

The fluorescent probe chlortetracycline (CTC) has been used to monitor the acquisition of the capacitated state of spermatozoa, first in the mouse, and then in other species, including man. Although it is not clear what is the basis of the staining, use of CTC together with fluorescent microscopy allows for the distinction of three functional states which have been correlated to the ability of sperm to fertilize oocytes: fresh uncapacitated sperm, capacitated acrosome-intact spermatozoa, and acrosome-reacted sperm. Thus, three sperm subpopulations can be distinguished with CTC and one important feature is that it can identify one that has apparently completed capacitation but has not yet undergone acrosomal exocytosis. Incubating spermatozoa under capacitating conditions, and using CTC together with a vital stain (e.g., Hoechst 33258), it is possible to quantify the proportion of live, capacitated-acrosome intact sperm. If sperm are incubated further, or are stimulated with ligands thought to be natural inducers of acrosome reaction, such as progesterone or the zona pellucida, then exocytosis in response to stimulation can also be quantified.

Occurrence of capacitation can also be monitored by changes in sperm lipids. Capacitation involves changes such as loss of cholesterol, destabilization of the sperm membrane, exposure of specific phospholipids from the inner membrane leaflet, activation of phospholipases and changes in composition of membrane phospholipids. Some of these changes occur very rapidly and they have been identified using specific fluorochromes and flow cytometry or with a series of methods for lipid biochemistry and enzyme (phospholipase) activation. Some of these methods, especially those involving flow cytometry are used to assess capacitation in the research laboratory. Changes in monosialotetrahexosylganglioside (G_{M1}) localization patterns that take place upon completion of capacitation in mouse and human sperm have been identified and recently proposed as the basis for a microscopy-based test in human spermatozoa. The test has been validated and was found to be indicative of male fertility; importantly, it renders information that is independent of traditional semen measures (Moody et al., 2017).

During capacitation there are also changes in the pattern of phosphorylation of sperm proteins. Ever since the discovery that during capacitation there is an activation of the cAMP/protein kinase A (PKA) pathway that results in phosphorylation of substrates and also tyrosine phosphorylation in an additional series of substrates, efforts have been made to take these proteins as markers of capacitation. Although the identity of the phosphorylated proteins is largely unknown, the PKA- and tyrosine kinase-mediated phosphorylation serves as a tool to understand changes supporting (or inhibiting) capacitation. This is a useful approach that can be used as a complement (or as a replacement) of other approaches used to assess capacitation, such as the time-consuming CTC staining. Nonetheless, electrophoresis and Western blotting is also time-demanding and requires a specialized setting.

Thus, other means to assess the phosphorylation status of proteins has been explored, including the use of direct microscopic examination of spermatozoa labeled with antiphosphotyrosine antibodies conjugated to fluorescent probes. A similar approach, but using flow cytometry to quantify changes in proteins phosphorylated in tyrosine, is an alternative that deserves standardization for use in future functional tests.

Proteomics techniques allow for the identification of protein content of spermatozoa at different stages and may provide information on dynamics of sperm cell function and identification of relevant marker proteins. This is particularly important in spermatozoa because these modifications take place in the absence of gene transcription and translation and, thus, are the result of post-translational processes such as phosphorylation. Studies have examined proteomes of sperm from different species (mouse, rat, human, bull, ram, stallion, boar) and comparisons using quantitative methods have addressed differences between mature and immature spermatozoa, epididymal versus ejaculated sperm, fresh and frozen spermatozoa, and high- and low-fertility spermatozoa. A few studies have attempted to identify variation due to capacitation, mainly in boar spermatozoa, and many proteins were found to vary in their abundance between capacitated and non-capacitated spermatozoa, although the function of many are not known. Proteins identified as being more abundant in capacitated spermatozoa have various roles connected to metabolism, protection from oxidative stress, motility regulation and sperm-egg interaction. Thus, these proteins may perhaps serve as biomarkers for functional tests that can assess and predict fertility (Rahman et al., 2017). Little has been done yet to compare the abundance of these markers with male fertility or litter size, although, interestingly, some initial attempts have revealed two important points: There may be an association between abundance of certain protein markers in high fertility animals when comparing expression profiles between males rendering high or low fertility results. However, not all the protein markers may be informative when running subsequent field trials trying to discriminate (predict) fertility in males. In bulls, only a subfraction of all the proteins identified to change during capacitation were significantly correlated to fertility. On the other hand, in boars, it was possible to identify proteins in capacitated sperm that correlated with litter size whereas others correlated with male fertility. Overall, there are differences in proteins between males with low or high fertility or litter size, and the predictive value increases when the proteins of capacitated sperm (as opposed to non-capacitated sperm) are taken into consideration in the analyses.

Functional Tests for the Acrosome Reaction

The status of the acrosome (i.e., presence, damage, or absence) has been examined using a variety of methods ever since it was realized that this exocytotic granule is required at some point in the train of events leading to fertilization. The acrosome contains enzymes that, upon release during acrosomal exocytosis, help the sperm traverse the cellular and cellular coats of the oocytes. So, it is important that the integrity of the acrosome is preserved until the sperm reaches the vicinity of the oocyte. The status of the acrosome can be examined using phase contrast optics in species with prominent acrosomes (ungulates, many rodents) but requires staining in other species. In general terms, staining of the acrosome could be done with or without fixation and employing a variety of dyes, including fluorescent ones, and examination under the microscope. More recently, methods to stain acrosomes and examine them by using flow cytometry have been developed; they are generally combined with a dye that can distinguish live-dead cells thus making it possible to follow changes in the four sperm populations.

Although exocytosis of the acrosome occurs subsequent to capacitation, and the latter is required for the former, exocytosis can be triggered using molecular probes, in the presence of extracellular Ca^{2+} , even in uncapacitated spermatozoa. The ability of sperm to respond to probes such as the Ca^{2+} ionophores A23187 or ionomycin, and the assessment of acrosomal status by a variety of methods, has been used as the basis of tests to identify the sperm's ability to undergo the acrosome reaction in efforts to distinguish potential fertilizing capacity (or at least, functional competence). Other probes, or metabolites involved in signaling processes underlying the acrosomal exocytosis, have been examined for their ability to trigger or enhance exocytosis in capacitated sperm. Thus, analogs of cAMP, inhibitors of phosphodiesterases, diacylglycerol kinase, diacylglycerol lipase, protein kinase A or C, fusigenic lipids, or modulators of phospholipase C or A_2 , among others, have been used (alone or in conjunction with ionophores/ Ca^{2+}) to probe for various pathways leading to exocytosis. However, most of them have not been incorporated, on a regular basis, in the design of tests to examine functional capacities of spermatozoa. Induction of acrosomal exocytosis by natural ligands (progesterone, zona pellucida) has been tested in spermatozoa capacitated under appropriate conditions.

Other Functional Tests

There are a series of methods for flow cytometric evaluation of plasma membrane and acrosome integrity, mitochondrial membrane potential, lipid stability or peroxidation and intracellular Ca^{2+} content, which serve to assess effects of storage conditions or in preparation for fertilization. These traits are assessed mainly in a research set-up and have not yet being incorporated as diagnostic tools of male fertility.

There has also been interest in quantifying oxidative stress because it is a known cause of impairment of sperm function. Reactive oxygen species (ROS) appear to take part in sperm capacitation but an excess may impair membrane integrity, sperm motility and it can damage sperm DNA. Little use is made of the quantification of ROS or antioxidants in a clinical set-up but these parameters have receive attention in the investigation of conditions that affect sperm storage by cryopreservation. The production of ROS can be examined using various methods, including some based on chemiluminescent detection using luminol, or flow cytometry with various fluorochromes that serve to quantify generic intracellular ROS or mitochondrial superoxide. There is also a simple inexpensive method, based on a nitro blue tetrazolium test, which can be assessed microscopically and that could be incorporated to the

clinical andrology laboratory. Nevertheless, there is still debate as to the merits of measuring ROS because of the limited evidence available regarding standardization and links with pregnancy outcomes.

Combination of flow cytometry and image analyses will be very useful in the future for the analysis of cell subpopulations with the possibility of adding localization of changes taking place in sperm cells.

Functional Tests for Sperm–Oocyte Interactions

The best estimate of fertilizing ability is perhaps that obtained through the use of artificial insemination, in which most sperm functions come into play, or in vitro fertilization, which still assesses many sperm functions with the exception of factors that influence sperm transport. However, artificial insemination can be used as a test method in domestic species, particularly bulls, rams or boars, but it is not available for other species for a variety of reasons. Alternatives to test fertilizing capacity in the laboratory, through tests of gamete interaction, have been examined.

Sperm–zona pellucida binding assays were developed for human sperm in an attempt to identify cases in which patients could be directed to artificial insemination or ICSI (Oehninger et al., 2014). Although the results of some of these assays correlate significantly with fertilization in vitro, they have some drawbacks, because they require human material, such as intact eggs or zonae pellucidae, and they are technically and time demanding. Two of these assays, the sperm–zona binding assay, and the hemizona assay, provide clinically useful and prognostic information regarding sperm competence for fertilization in IVF, according to a meta-analysis. The hemi-zona assay also resulted predictive of intra-uterine insemination in couples with male factor infertility (Oehninger et al., 2014). The hemizona assay includes a comparison of two populations of fertile and infertile spermatozoa in the same assay using matching halves of human zonae from an oocyte with no developmental potential (e.g., salt-stored).
